Reactor materials are not perfect crystals. In the absence of properties-defective structures, many fuel performance codes are modeled using values from databases that have been measured or calculated for perfect crystals. It is important that the new models incorporate point, line, 2D, and 3D defects (Phillips 2001). Models of dislocations and fracture can play a central role in improving the finite element simulations of heat and species transport in nuclear fuel elements.

The phase stability of nuclear fuels, especially during transient regimes, is a subject of concern for nuclear energy industry and regulators. Uncertainty evaluations of rather simple phase diagrams, such as UO₂ – PuO₂, revealed that the solidus and liquidus lines are known with an error as large as 100 K (Stan and Reardon 2003). Ceramic fuels tend to be less likely to melt but may experience local phase transformations. Metallic fuels are more at risk due the presence of low temperature eutectics in their phase diagram (Hecker and Stan 2008) and the potential for redistribution of the constituents in the fuel rod. Some structural materials, such as cladding alloys, are also at risk during transient regimes. Since temperature and pressure are the control parameters in most processes, the Gibbs free energy of all phases is the critical thermodynamic property for phase stability calculations (Lindemer and Besmann 1985). When taking into account the fission products and the chemical dynamics of the fuel material, it becomes necessary to study systems with five to ten components to achieve a good description of the thermo-chemical properties of the fuel. Although free energy functions are available for many phases of interest (mostly oxides and alloys) more work is necessary to cover the nitrides and the advanced (minor actinide containing) fuels. In France, the Atomic Energy

Cross section of UO_2 fuel rod operated at a linear power high enough to cause extensive melting [LYO65]

Commission (CEA) has developed one of the most advanced databases for thermodynamic properties of fuels, named FUELBASE. Similar studies are under development in USA, at the National Institute for Standards and Technology (NIST).

Reactor materials are subject to severe radiation environments and their thermal, chemical, and mechanical properties change significantly with time and irradiation level. The major factors that influence the properties are temperature, stoichiometry, and microstructure (especially porosity and point defects). It was discovered early on (Lyons et al. 1965) that the accumulation of fission products in gas bubbles can decrease the heat transfer, leading to overheating of the fuel element and local melting (► Fig. 45).

Recent work at LANL was focused on irradiation effects on properties such as thermal conductivity, oxygen diffusivity, and thermal expansion. The methods cover a large spectrum of time and space scales, from electronic structure to atomistic, to mesoscale, to continuum (Stan et al. 2007). As an example of the coupling between atomistic models of point defect and thermo-chemical method, ► Fig. 46 shows a calculation of UO_{2+x} nonstoichiometry as a function of partial pressure of oxygen. The model is further used to predict point defect concentrations and oxygen diffusivity at various temperatures and oxygen pressures.

In these results, the migration rates of the oxygen interstitials and vacancies are calculated using activation energies obtained from experiments (Kim and Olander 1981).

Another example, this time at the mesoscale, is given in ► Fig. 47 and shows a comparison of simulated and experimental gas bubbles formation and evolution (Hu et al. 2007, 2009). This type of simulations requires intensive computation and is most suitable for high performance computing. However, at the time of this writing, no parallel phase field codes for this purpose was available. Current work in this area in USA, France, and Japan is focused on developing models of advanced, multicomponent fuels that contain transuranic elements (minor actinides) as well as advanced structural materials, such as oxygen deficient steels (ODS) (Samaras et al. 2009). The next step is to include fission products as system components.

Uranium-oxide-based nuclear fuels are commonly used in thermal, light water reactors and have been recently considered as the potential fuel for fast, breeder reactors. As shown in ► Fig. 48, the oxide nuclear fuel rods consist of oxide fuel pellets stacked in a cylindrical

■ Figure 48

Schematic of the nuclear fuel rod and assembly (United States Nuclear Regulatory Commission, Emergency Preparedness)

metal cladding and then bundled in a fuel assembly, operating at temperatures up to 2,000 K (United States Nuclear Regulatory Commission, Emergency Preparedness).

There are many additional fuel types, and evaluating them all is beyond the scope of this work. The most popular, with the richest history, are based on uranium oxide (Belle 1961). Plutonium oxide was introduced as a component of the mixed oxide fuels (MOX) for reasons that include reprocessing of the weapons grade plutonium metal for energy purposes. Metallic fuels have been investigated with success but are less popular (Hecker and Stan 2008).

Given the tremendous resources (cost, time, people) required to conduct experiments in the nuclear reactors, the studies of nuclear fuels are sometimes replaced by studies of surrogate ceramic materials, such as ceria (CeO_2) or zirconia (ZrO_2). The problem with such studies is the transferability of the results. For example, although ceria is considered a good surrogate for plutonia (Stan et al. 2002) it is not clear if the study of the fission product diffusion mechanism in the $\text{UO}_{2+x} - \text{CeO}_{2-x}$ system can provide a definitive answer to the questions related to fission products accumulation in a mixed oxide fuel $\text{UO}_{2+x} - \text{PuO}_{2-x}$. Another reason to use lower atomic number elements such as Ce as surrogate for high atomic number actinides (U, Pu, Th, etc.) is the complexity of the ES calculation. High performance computing may help completing the necessary calculations to fully describe properties of complex, actinide materials and reduce the need for surrogates.

Researchers at Los Alamos National Laboratory (LANL) have examined the influence of temperature and stoichiometry changes on the UO_{2+x} fuel properties and on the coupling of heat and species transport in a fuel element with stainless steel cladding (Ramirez et al. 2006). The objective was to improve the understanding of fuel damage and performance. Several parametric models have been created for these properties using the temperature, pressure, burnup, and other reactor parameters (Cristea et al. 2007; Stan and Cristea 2005; Stan et al. 2007). The main advantage of the LANL models is the fact that they include the dependence of the properties on the stoichiometry x in UO_{2+x} .

The finite element simulations of coupled heat and oxygen transport (Ramirez et al. 2006) were performed using COMSOL Multiphysics^{texttrademark} which provides an ideal tool for studying coupled phenomena and allows for mesh and time step refinement in 3D configurations (► Fig. 49). Quadratic Lagrange elements and a nonlinear iterative technique with a nested unsymmetric multi-frontal (UMFPACK) linear solver have been used to solve the coupled heat and species equations.

The steady-state parametric studies were focused on determining the centerline temperature in the fuel rod as a function of non-stoichiometry and the rate of heat generation during

■ Figure 49

Representative “slice” of the computational domain, showing a 22.5 deg. angular sector of the fuel element. The mesh was refined at the gap, where temperature and stoichiometry gradients are steeper.

■ Figure 50

FEM simulations of heat transport in a fuel element. A disc-shaped macroscopic defect was placed in the fuel pellet to simulate the effect of a macroscopic defect. The simulation predicts that the temperature (color scale in K) will locally increase by 190 K (Lyons et al. 1965; Stan et al. 2009)

fission. Given the strong temperature gradients in the reactor, the effect of thermally driven diffusion of species, also known as the Soret effect, had to be included. The results show that the counterbalancing of the Soret (Janek and Timm 1998; Korte et al. 1997) and Fickian fluxes is responsible for the variation of oxygen concentration in the fuel pellet (Ramirez et al. 2006). The simulations demonstrate that including macroscopic defects in the fuel pellet can lead to significant changes in the local temperature. Additional simulations involved transient regimes and examination of the time lag in the response of the temperature and non-stoichiometry distributions with respect to sudden changes in heat generation rate intensity and oxygen removal rate. Current work includes studies of the effects of macroscopic defects such as porosity (🔍 Fig. 50) and simulations of fuel-cladding interactions involving simulations on high performance computational platforms.

6.3.4 Fuel Performance Codes

Evaluating the properties of the fuel and predicting the changes caused by the reactor environment is a challenging task. Most nuclear technological processes are complex combinations of

the above reviewed properties and phenomena. As an example, sintering of ceramic fuel materials involves heat and mass transport, phase transformations, irradiation effects, and changes in mechanical properties. A complex simulation of the sintering process must be developed as soon as possible, to assist with fuel design and fabrication.

Fuel performance is one of the areas that already benefited from models and simulations. A fuel performance capability (FPC) consists of a computer code or a set of codes that contain models of fuel properties and are able to simulate phenomena in the nuclear fuel during operation. In a more general version of this concept, the fuel performance is evaluated in the fuel element (fuel plus clad) and the applicability is extended to cover manufacturing and storage. The FPCs are sometimes classified according to their history and complexity into “generations” starting with Generation 1 (1D, serial codes based on empirical models) and ending with Generation 4 (future, parallel, 3D codes that contain theory-based models).

Besides extensive experimental post irradiation examination (PIE), the fuel performance capabilities are increasingly complex tools in support of fuel characterization and optimization (Aybar and Ortego 2005).

For this section, we have extended the review of FPCs and found that most countries tend to develop their own simulation capabilities. Here is a list (by no means exhaustive) of some of the most popular fuel performance codes: COMETHE (Belgonucleaire, Belgium), COPENIC (FRAMATOME, Germany), ENIGMA (British Energy, BNFL, UK), FALCON (EPRI, USA), FRAPCON (PNNL, USA), FRAPTRAN (PNNL, USA), LIFE (ANL, USA), MACROS (SCK-CEN, Belgium), ORIGEN (ORNL, USA), PARFUME (INEEL, USA), SPHERE (PSI, Switzerland), and TRANSURANUS (ITU, Germany).

The major drawback of most FPCs is the fact that they are too dedicated to a specific fuel form and composition. The use of empirical correlations in describing material properties and the much simplified description of heat and mass transport phenomena make extrapolations and information transfer impossible. In order to achieve a consistent predictive character, many codes are moving away from empirical models and include theory-based models.

Neutron transport *fission processes*, although not the main subject of this section, are a critical component of fuel behavior. Phenomena such as fission products release, diffusion, and accumulation have a strong impact on material properties and influence the heat and mass transport. Up to now, due to computational power limitations, nuclear reactions have been decoupled from the study of material properties. For example, in many FPCs, the heat generated during fission is only added as a source term to the finite element calculations. Modern high performance computing opens the door for fully coupled simulations of neutrons, heat, and species transport in the reactor.

Since in the nuclear fuels community heat and species transport phenomena have been studied in much more detail, most commercial fuel performance codes, such as FRAPCON (FRAPCON simulation code) have capabilities for a global evaluation of heat transfer and species diffusion simulations. Some codes can address transient regimes and solve for the time-dependent transport equations. More challenging are the simulations of heat transfer in heterogeneous materials, with porosity and defects distributed in the fuel rod according to experimental data.

Although extremely important, the diffusion of fission products is not well understood due to the lack of “in situ” characterization methods. Also, the role of diffusion at the grain boundaries is still unclear. This phenomenon is strongly related to microstructure evolution and must be further studied using experimental and theoretical tools. Unfortunately, accurate models of

microstructure evolution (point defects and dislocations along with grain boundary movement) during service are most often lacking in FPCs.

Our review shows that many codes do not address the thermo-chemistry of chemical reactions, such as oxidation/reduction or the effect of the coolant on the radiation-enhanced corrosion of reactor materials. One exception is TRANSURANUS, which accounts for radial redistribution of oxygen in fast breeder reactor fuels.

All FPCs focus on thermo-mechanical properties and phenomena. Still, mechanical phenomena that involve 3D simulations, such as pellet fragmentation and clad–pellet interactions are difficult to address at this stage. Most codes do not allow for simulations of large changes in the gap and clad geometry. That leads to simulation tools for rather idealized geometries, difficult to validate against experimental results on real fuel elements.

From a computational point of view, a major problem is the fact that most FPCs cannot run in parallel on high performance supercomputers and use simplified, and often empirical, models reflective of the limited computational horsepower available to these codes at the time they were created. This both increases the computation time and reduces the computation fidelity. It is unfortunate that current FPCs do not take advantage of this technology and are still running on personal computers. There is, therefore, a tremendous opportunity for moving to high performance computing for nuclear fuels applications and increasing their fidelity and speed. Each of the top 500 fastest supercomputers in the world today can now reach over a teraflop per second. At the time of writing this article, the number one position in the world was claimed by the Roadrunner computer at LANL (Roadrunner supercomputer: <http://www.lanl.gov/roadrunner>), a joint development of Los Alamos, IBM, Toshiba, and DOE's National Nuclear Security Administration (NNSA). The second place position was held by the Jaguar computer at Oak Ridge National Laboratory. The European Union and Japan are also working on systems that will compete for first place in the future. Already, neutron diffusion calculations, as well as some safety and security simulations, are performed on such resources. FPCs can and must become more complex to run on supercomputing networks. This involves innovative code design and advance algorithms which are capable of taking advantage of the hardware developments. The codesign of such an application with emerging computational architectures, along with improvements in physics models and numerical methods made available by such systems, provide a path for enhanced fidelity and performance, pointing toward predictive capability and quantified uncertainties.

Another major difficulty is the lack of compatibility between the FPCs. The codes have very useful and complementary features but cannot be coupled and executed together, nor even easily feed information to each other. Software engineering issues prevent a full coupling of the codes and modifying them to run in parallel very difficult, as required for large-scale simulations on advanced computational platforms. To solve this problem, France has developed an integrating platform SALOME (<http://www.salome-platform.org/home/presentation/overview/>) intended to facilitate the creation of industrial simulation applications. It is currently used by CEA for nuclear energy simulations that incorporate independent fuel performance and reactor codes. Using this platform and the associated codes, CEA researchers have been able to produce integrated, multi-scale simulations in irradiated fuel elements.

The question remains: is it better to attempt to modify existing codes to make them structured, run in parallel on high performance computational platforms, and possibly become object oriented, or create new codes from scratch? The answer to this question is complex, and ultimately depends on available human resources and expertise and how the code will be used.

Figure 51

Preliminary design of the advanced fuel performance capability (AFPC) (Stan 2005; Stan et al. 2009)

Modifying a large existing legacy code can be very difficult and time consuming, and in some cases, impossible, due to the limitations of the data structures embedded in the code. Repeatability of computational results achieved from a re-factored legacy code can also be an issue, particularly if previously unknown errors are found. However, legacy codes represent a wealth of integrated experience and knowledge that require preservation. Creating a new code from scratch is also a difficult endeavor for different reasons – validation of an entirely new code with no historical pedigree being one of the most difficult. There are several options for developing new fuel performance capabilities, going from integration of existing codes to the design of new ones.

The real answer to this question lies in a combination of approaches. It is particularly important to carefully plan verification and validation activities as empirical methods are replaced with more advanced and accurate methods on faster computers. It is given that, as legacy codes are re-factored and reborn, previously achieved results will change due to an unknown canceling of errors that occurred in legacy codes.

This challenging endeavor involves both model development and software engineering.

► Figure 51 shows a preliminary design of a new generation, advanced fuel performance capability (AFPC) (Stan 2005). To address the nuclear fuels material properties and phenomena, the code must include at the minimum the following components:

- Neutronics (fission and neutrons diffusion)
- Heat transfer (conduction, convection, and radiation)
- Mass transport (species diffusion and gas accumulation)
- Thermo-mechanics (deformation, such as swelling)

- Fluid flow (to model the coolant, if necessary)

There are also requirements related to numerical algorithm design, uncertainty quantification, and software engineering. For example, using nested (linear + nonlinear) solvers, multilevel preconditioning, running parallel on large-scale supercomputers, and easy adaptation to hybrid platforms are all requirements. Additionally, the code must interact with an external database that is continuously updated with the most advanced models of fuel and material properties and the necessary nuclear data.

Another vital component of this strategy is creating the framework for active national and international collaborations. For example, the Materials Models and Simulations for Nuclear Fuels (MMSNF) workshop series (<http://itu.jrc.ec.europa.eu/index.php?id=36&type=&iEntryUID=164&iEntryPID=68>) and the OECD/NEA Working Party on Multi-Scale Modelling of Fuels and Structural Materials for Nuclear Systems (WPMM) (<http://www.nea.fr/html/science/wpmm/index.html>.) have the goals of establishing multi-scale models and simulations as validated predictive tools for the design of nuclear systems, fuel fabrication, and performance.

Given the improvements in precision and accuracy, and the full validation of the methods, the computer simulation capabilities (sets of codes) are likely to soon become part of the fuel qualification process. The most challenging aspect of this process is building the trust of the national regulatory agencies. To achieve the necessary level of confidence, the codes must be thoroughly validated against experimental data.

6.3.5 Conclusions

The radiation environment specific to nuclear reactors continuously alters the properties of nuclear fuels and structural materials. There is a need for an integrated theoretical, experimental, and computational approach to develop a fundamental understanding of properties of complex materials in the reactor environment. A key component of such approach is relating the models of thermo-mechanical properties such as enthalpy, heat capacity, thermal conductivity, and thermal expansion, to parameters such as temperature, composition, porosity, pressure, and irradiation level. Such a methodology can lead to improved tools for simulation and predicting reactor phenomena, including heat transfer, phase stability, species diffusion, and fission products retention.

In this work we distinguish between models (mathematical representations of how materials perform) and simulations (the process of running computer programs to reproduce, in a simplified way, the behavior of materials). Models and simulations address a wide range of space and time scales, starting with the nucleus to the electronic structure, atomistic, nanoscale, mesoscale, all the way to the fuel element size (centimeters), and from picoseconds to seconds, all the way to the operating and storage characteristic times (months, years).

A review of recent model and simulation results in USA, Europe, and Japan shows the importance of accounting for radiation effects on properties such as thermal conductivity, oxygen diffusivity, and thermal expansion. By coupling atomistic models of point defect and thermo-chemical methods into a model of oxygen diffusivity in UO_{2+x} , predictions of point defect concentrations and fuel stoichiometry at various temperatures and oxygen pressures are now available. Based on the same models, the simulations of coupled heat transfer and species diffusion demonstrated that including the dependence of thermal conductivity and

density on composition can lead to changes in the calculated centerline temperature and thermal expansion displacements that exceed 5%.

The major drawback of most commercial fuel performance capabilities (FPCs) is the fact that they are dedicated to a specific fuel form and composition. The use of empirical correlations in describing material properties and the much simplified calculations of heat and mass transport make accurate extrapolations very difficult. Many codes are moving away from empirical models toward including theory-based models, to achieve a consistent predictive character. From a computational point of view, a major problem is that the majority of commercial codes are not designed to take advantage of the high performance (tera- and petascale) computational platforms. In this work we propose a preliminary design of an advanced fuel performance capability (AFPC) that is able to interact with the material properties database and provide an efficient way of performing multi-physics simulations of coupled phenomena, such as neutron, heat, and chemical species diffusion.

The most important resource for achieving the goal of conducting high performance simulations of material's properties in nuclear reactors is the people: computer and computational scientists, physicists, chemists, and materials scientists. Their contribution is essential in ensuring the relevance of the modeling and simulation work for the nuclear engineering community. A large pool of experts is necessary to cover all theoretical, experimental, and computational tasks. That can be achieved by including "Models and Simulation" in the materials science and nuclear engineering programs at universities all over the world and by increasing national and international collaborations.

We hope that, given the improvements in precision and accuracy and the full validation of the models, the high performance computer simulations will soon become part of the fuel qualification process.

7 Conclusion and Open Issues

We have presented in this chapter a short introduction to high performance computing and some illustrations of this use in nuclear engineering.

This chapter could neither cover all the fields of parallel computing nor all the uses of HPC in nuclear engineering. We have tried to figure out how HPC tools can be useful and even sometimes be the unique way to progress and go beyond some limits.

Of course the domain of computer science and HPC permanently moves, and it is a tricky exercise to describe the state of the art of this domain. We do not have the pretention to be exhaustive but we have tried to show the major challenges involved in the field of nuclear energy and HPC. But there are still many of them which are open issues for HPC in nuclear engineering.

First of all, concerning architecture and processors, one of the biggest challenges is to reach the desired performances (many petaflops, exaflops, etc.) within a controlled thermal envelope. Moreover, tomorrow's architecture will be based on hundreds of thousands of cores, and the failure probability will grow dramatically. Thus, in order to use these supercomputers, fault tolerance will have to be taken into account at different levels: hardware level, middleware level, and application ones. Another great challenge is the programmability of these architectures, since the number of parallelism levels is increasing more and more (multi-instructions in one core, multi-threading between cores in a same node, concurrency between cores and accelerators, task parallelism between nodes, etc.) and it becomes more and more difficult to express parallelism in an efficient way.

All these hardware and software challenges have of course direct consequences on applications, especially on the design and the methods to “embed parallelism” into scientific applications. Thus, applications have to be more and more modular and versatile in order to be as polymorphic as possible and at the same time the most efficient as possible for a given parallel architecture at a given time and able to move to other parallelism models for the future, since the code life cycles are much more longer than supercomputer architectures.

Abstract: The analysis of the behavior of light water reactor (LWR) fuel rods is described. The properties of relevant fuel and cladding materials are discussed and numerical data are given. The basic phenomena taking place in pellet-in-cladding nuclear reactor fuel are described systematically, including neutronic aspect of the fuel, the thermal and mechanical behavior, the fission gas behavior, and radiation effects. Finally typical phenomena and issues in the design and licensing of LWR fuels and their effects on fuel behavior are discussed: the high burnup structure, pellet-cladding interaction, pellet-coolant interaction, loss-of-coolant accidents (LOCA), and reactivity-initiated accidents (RIA).

1 Introduction

The nuclear fuel is the basic element of a nuclear reactor core, providing the material for generating the energy that is used for the production of electricity or process heat. The process taking place in the nuclear fuel is fission, by which a fissile nuclide disintegrates in two fragments after it has captured a neutron. There are two basic nuclear fuels that fission with thermal neutrons ($E < 1$ eV): uranium (^{235}U) and plutonium (^{239}Pu and ^{241}Pu). Of these, ^{235}U is the only one found in nature, its natural abundance being 0.72%. ^{239}Pu is generated in reactor from ^{238}U , when a ^{238}U atom captures a neutron. These two elements produce basically all the nuclear energy generated in the current generation thermal neutron reactors (light water reactors, heavy water reactors). Fast neutrons ($E > 10$ keV) can also be used to fission uranium and plutonium, and eventually other actinides in fast neutron reactors (FNRs). These reactors can also be used to breed fissile plutonium from uranium. An additional fuel cycle utilizes ^{233}U , which is created when ^{232}Th captures a neutron.

The fission process taking place in the reactor core produces about 200 MeV of energy per fissioned atom. This energy is transferred for the majority as kinetic energy to the two fission fragments that are produced. During the trajectory from the site of their creation to the site where they come to a halt, the fission fragments transfer their energy to the crystal lattice of the host material, principally by exciting thermal vibrations in the lattice. At the same time the fission fragments knock atoms from their crystal lattice sites causing lattice damage that leads to material degradation.

The science and technology of nuclear fuel deals principally with describing the fundamental processes that are governing and affecting the heat transport in the fuel, and that are limiting the in-reactor lifetime of a fuel rod or fuel element. This is a complex set of processes depending on the initial state of the material, the linear power, the burnup, and the operating temperature. Since the operation of the first reactors in the 1950s, the need for an understanding these processes has been manifest and an enormous knowledge base has been created. This knowledge base is built on observations of irradiated nuclear fuel from commercial reactors or irradiation tests in research reactors by destructive and nondestructive examination, on separate effect studies performed in-reactor or out-of-reactor, and on theoretical calculations and simulations.

Uranium oxide fuel in the form of pellets-in-clad type fuel rods is used in all light water reactors (LWRs) and heavy water reactors (HWRs) around the world, which constitute more than 90% of the installed nuclear power. Due to the industrial relevance, extensive studies on conventional uranium oxide fuels have been performed and an adequate knowledge of the behavior now exists to ensure safe and economic operation of present-day reactors, as will be detailed in this chapter. In some countries, especially in Europe, also mixed oxide fuel, (U,Pu) O_2 , is used

to fuel LWRs with the intention to consume separated plutonium, originally intended for fast reactor operation. Also for MOX fuel an acceptable understanding of the fuel behavior exist.

The goal of this chapter is to describe the fundamental issues in the science and technology of nuclear fuel required to analyze and simulate the in-pile behavior of nuclear fuel. The emphasis will be on pellet-in-clad type oxide fuel for LWRs, which represent the majority of power reactors operated presently.

2 The LWR Fuel Element: A General Outline

2.1 The Fuel Pellet

The basic building block of the traditional pellet-in-pin fuel element is the fuel pellet. The fuel pellet is a cylindrical compact produced from a powder, that is, UO_2 or $(\text{U,Pu})\text{O}_2$. It can be a full pellet, as is normally the case in Western boiling water reactors (BWR) and pressurised water reactors (PWR), or an annular pellet as is the case for the Russian pressurized water reactors (known under the acronym VVER).

In case of UO_2 fuel, the starting powder is the product of the mining-conversion-enrichment chain, during which the uranium is purified and eventually enriched in ^{235}U to meet the specification. The uranium dioxide is produced from UF_6 in either a dry or wet process. In the dry process, the solid UF_6 is sublimed to its gaseous form and is reacted with superheated steam and then passed through a rotating drying kiln to produce UO_2 powder. In the wet process, the solid UF_6 is sublimed to its gaseous form and is bubbled through water to form UO_2F_2 , which is then mixed with aqueous ammonia causing the uranium to precipitate as ammonia-diuranate (ADU, $(\text{NH}_4)_2\text{U}_2\text{O}_7$). The precipitate is dried and calcined to form U_3O_8 , which is then further reduced in a cracked ammonia atmosphere to form UO_2 . The UO_2 powder is blended in a batch mode, where binder materials, lubricant and eventually pore formers are mixed with the fuel (► *Fig. 1*). The powder is cold pressed at 150–300 MPa to form “green” pellets of 50–60% theoretical density (TD). The green pellets are then placed in a furnace and sintered in a hydrogen–argon atmosphere at 1,600–1,700°C for 5–10 h to produce pellets of 95–96% TD. Eventually, further annealing in hydrogen gas ensures a final product of the correct stoichiometric composition. Finally, a centerless grinding is applied to adjust the diameter to the specified dimensions. Although designs vary from core to core, typical final dimensions of LWR fuel pellets are on the order of 1 cm in diameter and 1–2 cm in height.

In general, reactor grade UO_2 fuel pellets must meet a number of very specific criteria related to their physical state (Assmann 1982):

1. *Density and porosity:* During the high-temperature sintering the density of the compacted pellet changes to above 90% TD. A fully dense material is not wanted as it cannot accommodate the radiation-induced matrix swelling nor the fission gases that are produced during irradiation; a too low density cannot be tolerated as it will impact the thermal conductivity (see below). In practice a density of about 95% TD is the best compromise. This means that the pellet contains about 5% porosity. The pore structure and distribution in the pellet should be homogeneous, with the ideal mono-modal pore size between 1 and 10 μm . Since some starting powders have a high sinterability and contain only little intragranular porosity, pore formers can be added to control the porosity. In that case a bi-modal pore structure is obtained made of small intergranular pores and larger pores resulting from the pore former.

■ Figure 1

Schematic representation of the nuclear fuel pellet fabrication processes

2. *Grain size*: The grain size of the UO_2 strongly depends on the powder properties and the sintering conditions. Normally a mono-modal grain size distribution is obtained, with average grain size in the order of 8–12 μm . Additives (e.g., chromium oxide, aluminosilicate, or niobium oxide) can be used to increase the grain size, which can have a positive impact on the in-reactor behavior, as a larger grain size can improve fission gas retention.
3. *Stoichiometry (O/M)*: The stoichiometry (or oxygen-to-metal ratio, O/M) is an important parameter for the UO_2 fuel as it strongly affects the physicochemical properties, as discussed ▶ Sect. 3. The sintering process is a reductive process, normally performed in an argon/hydrogen gas mixture, that yields $\text{O/M} = 2.00$ as required for LWR fuel.
4. *Dimensions and surface roughness*: It is evident that pellets with defects cannot be accepted for fuel rod fabrication. Furthermore the outer dimensions of the pellets and the outer surface roughness must be assured within a small tolerance to the specification in view of the fuel rod characteristics. Since after pressing and sintering the pellets generally do not fulfill this requirement, a (centerless) grinding step is generally used to achieve conformity with the specification.

In the case of mixed oxide fuel (MOX), powders of uranium oxide and reprocessed plutonium oxide are mixed mechanically. Since a homogeneous distribution is the aim and this is not reached by simply co-milling of the powders, various processes have been developed, two of which are currently used on an industrial scale. Since fissile plutonium (^{239}Pu and ^{241}Pu) is

approximately equivalent to ^{235}U on a gram for gram basis, equal weight percentages of ^{235}U in UO_2 and fissile plutonium in MOX are needed to reach the same discharge exposures. The total plutonium enrichment will however be higher because of the presence of non-fissile ^{240}Pu and ^{242}Pu isotopes.

The most widely used process to fabricate MOX fuel is the MIMAS (Micronized MASTER blend) process. The process consists of two steps, first a mixture of plutonium dioxide, uranium dioxide, and recycled scrap is finely grounded (● Fig. 2). The obtained powder is sifted and diluted in uranium dioxide until the desired plutonium content is obtained. This secondary mixture is pressed into green pellets and the green pellets are sintered to the desired density. In the SBR (short binderless route) process, the UO_2 and PuO_2 powders are mixed and milled in several stages in an attrition mill to obtain a homogeneous powder. In both processes, however, the distribution of plutonium in the final product is not homogeneous. Plutonium-rich spots can be observed in a matrix of $(\text{U,Pu})\text{O}_2$, though much more pronounced in the MIMAS fuel compared to the SBR fuel. A variation of the MIMAS process is selected for the Japanese MOX fabrication plant in Rokkasho-Mura, the master blend being produced from mixing of UO_2 and a UO_2 – PuO_2 mixture (50:50) obtained from reprocessing, avoiding the handling of pure PuO_2 .

■ Figure 2

Schematic representation of the MIMAS and SBR processes used for the production of powders for mixed oxide fuel

Also fuels with dopants such as Gd are generally produced by powder technology. The technology is similar to that used for MOX fuel. First a master blend is made that is then blended down with UO_2 to the required Gd concentration.

In many LWR fuels, the pellets have dished faces (concave central recess) to anticipate for the radial anisotropic expansion behavior of the fuel pellets during irradiation. Also chamfering of the pellet faces is often used, as this eases loading into the fuel rod and also reduces the pellet-cladding mechanical interaction (PCMI) (► 6.2.1).

2.2 The Fuel Rod

The fuel rod (or pin) is the principal confinement of the nuclear fuel in the reactor core. The fuel rod is a cylindrical metallic sheath in which the stack of pellets is loaded. The size of thermal reactor fuel rods differs significantly between the various reactor designs (about 400 cm in length and 9–11 mm in diameter in PWRs, 400 cm in length, and 12–14 mm in diameter in BWRs) but in all cases zirconium alloys are used for the cladding. The fuel does not cover the complete length of the pins, but a free volume (plenum) is generally kept at the top of the pin to accommodate some release of fission gases. The pellets are kept in place by a plenum spring. To avoid contact between the top pellet and the spring, an insulator pellet (Al_2O_3) is placed in between. Similarly an insulator pellet is placed between the bottom fuel pellet and the lower end plug. The fuel rods are pressurized with helium (about 20–25 bar in PWRs and 3 bar in BWRs), to assure a good thermal conduction of the gap between the pellet and the cladding, and then end-capped with the upper end plug. A schematic drawing of a fuel rod is given in ► Fig. 3.

2.3 The Fuel Element

For the loading into the reactor the fuel rods are assembled into fuel elements (also called bundles or subassemblies), whose design vary strongly per reactor type, depending on the thermal–hydraulic and neutronic characteristics. In general three different geometries are used: square, hexagonal, and circular.

In western PWRs the fuel rods are assembled in a square geometry generally ranging between 14×14 to 17×17 (► Fig. 4). The fuel elements for the Russian VVERs in contrast have a hexagonal geometry, containing around 300 fuel rods. The fuel rods are kept together by a support structure that consists of the following elements:

- A top and a bottom nozzle, that support the element stability and directs the coolant flow. The nozzles are generally made of stainless steel (e.g., AISI 304L). The top grid is also designed to allow handling during loading and unloading.

■ Figure 3
Schematic representation of a LWR fuel rod

■ Figure 4

Fuel elements for BWR and PWR. ©AREVA, reproduced with permission

- Guide tubes, that are needed for the movement of the control rods, are made of zirconium alloy, as the fuel cladding.
- A central instrumentation tube for the introduction of core instrumentation. It is also made of zirconium alloy.
- Several axially spaced grids along the height of the assembly, to ensure the spacing between the fuel rods during irradiation. The spacer grids are made of zirconium alloy and are normally welded to the guide tubes and instrumentation tubes.

For boiling water reactors (BWRs) the fuel rods are generally assembled in a 8×8 to 10×10 square geometry and also kept together by spacer grids and supported by top and bottom nozzles (► Fig. 4). In modern BWR fuel bundles, there are either 91, 92, or 96 fuel rods per assembly depending on the manufacturer. Each element also contains several flow channels.

3 Properties of Oxide Nuclear Fuel

3.1 Structure and Thermal Expansion

Uranium dioxide (UO_2) has a cubic crystal structure, with uranium in a face centered array and the oxide ions occupying the tetrahedral holes. This cubic structure gives the uranium oxide

pellet uniform expansion properties. The lattice parameter of the UO_2 unit cell is 546.92 pm at $T = 293 \text{ K}$, which yields a theoretical density is $10.963 \text{ g}\cdot\text{cm}^{-3}$.

Upon heating, the UO_2 crystalline lattice expands. Martin (1988) evaluated the lattice expansion and recommended the following polynomial equations for solid UO_2 , as also selected by an IAEA expert group (IAEA 2006):

$$\begin{aligned} L/L_{273} = 0.9973 + 9.082 \times 10^{-6}(T/K) - 2.705 \times 10^{-10}(T/K)^2 \\ + 4.391 \times 10^{-13}(T/K)^3 \quad (273 < (T/K) < 923) \end{aligned} \quad (1)$$

$$\begin{aligned} L/L_{273} = 0.99672 + 1.179 \times 10^{-5}(T/K) - 2.429 \times 10^{-9}(T/K)^2 \\ + 1.219 \times 10^{-12}(T/K)^3 \quad (973 < (T/K) < 3110) \end{aligned} \quad (2)$$

The density of solid UO_2 can be derived from this equation using the formula

$$\rho(T) = \rho(273) \frac{L(T)}{L(273)} \quad (3)$$

using $\rho(273) = 10.963 \text{ g}\cdot\text{cm}^{-3}$ based on the recommended lattice parameter. For practical reason the density can be represented by the following polynomial equation

$$\begin{aligned} \rho(T) = 11.049 - 3.34 \times 10^{-4}(T/K) + 3.9913 \times 10^{-8}(T/K)^2 \\ - 2.7649 \times 10^{-11}(T/K)^3 \end{aligned} \quad (4)$$

Plutonium oxide (PuO_2) also crystallizes in the face centered fluorite structure and forms a solid solution with UO_2 in the complete composition range. The lattice parameter of PuO_2 is 539.60 pm at $T = 273 \text{ K}$, which yields a theoretical density of $11.46 \text{ g}\cdot\text{cm}^{-3}$. The thermal expansion of PuO_2 is almost similar to that of UO_2 and since UO_2 and PuO_2 form an ideal solid solution, Eqs. 1 and 3 can thus also be used for the $(\text{U}_{1-y}\text{Pu}_y)\text{O}_2$ solid solution. Carbajo et al. Carbajo et al. (2001) suggested that the density of $(\text{U}_{1-y}\text{Pu}_y)\text{O}_2$ at 273 K can be interpolated linearly between the two end-members, which becomes

$$\rho(273.15 \text{ K}) = 10.963 + 0.497y \quad (5)$$

with the density value for UO_2 used here.

The International Atomic Energy Agency (IAEA) expert group (IAEA 2006) gave recommendations for the thermal expansion of $(\text{U}_{1-y}\text{Gd}_y)\text{O}_2$ based on critical review of the existing experimental data. The recommended equation is

$$\begin{aligned} L(T)/L_{273} = 0.99866 + 7.2512 \times 10^{-6}(T/K) \\ + (2.0463 \times 10^{-13}y^2 + 3.4846 \times 10^{-11}y + 2.0653 \times 10^{-9})(T/K)^2 \end{aligned} \quad (6)$$

3.2 Thermal Conductivity

3.2.1 UO_2

The thermal conductivity is an important property of a nuclear fuel, as we will explain in [Sect. 5.2.3](#). UO_2 has a relatively poor thermal conductivity, which has a minimum at approximately $2,000^\circ\text{C}$ ([Fig. 5](#)). Many measurements have been reported for UO_2 and were carefully evaluated by an expert group of the IAEA ([2006](#)).

Conduction of heat in the pellets occurs by phonons or by the kinetic energy of electrons: $\lambda = \lambda_{ph} + \lambda_{el}$. At temperatures below 1,500 K the phonon contribution predominates. When applying the kinetic gas theory to the propagation of atomic vibrations (phonons) or quasi-particles, it appears that the phonon conductivity in the temperature range of interest can be expressed as

$$\lambda_{ph} = \frac{1}{A + BT} \quad (7)$$

where A corresponds to the scattering of phonons by imperfections such as point defects, line and planar defects, fission gas bubbles. The parameter B corresponds to the scattering by phonon–phonon (Umklapp) interactions. When the burnup (bu) in the pellets increases, the accumulation of point defects and fission products will increase the phonon scattering (A -term). The same happens if the fuel (e.g., UO_2) is doped with a neutron absorber such as Gd_2O_3 , or if a deviation from stoichiometry occurs ($x \neq 0$, where $x = |2 - O/M|$ and O/M is the oxygen-to-metal ratio in UO_2), that is, in general $A = A(bu, \text{Gd}, \text{Pu}, x)$.

[Equation \(7\)](#) also suggests that the thermal conductivity decreases with increasing temperature, which is the case for UO_2 up to about 2,000 K. Above this temperature the electronic contribution becomes important as a result of which the thermal conductivity slightly increases

■ Figure 5

The thermal conductivity of UO_2 , PuO_2 , $(\text{U,Pu})\text{O}_2$, and $(\text{U}_{0.9}\text{Gd}_{0.1})\text{O}_2$ as a function of temperature

again (► Fig. 5). The temperature dependent creation of electronic carriers leading to λ_{el} is typically expressed as (Harding and Martin 1989)

$$\lambda_{el} = \frac{C}{T^n} \exp\left(-\frac{W}{kT}\right) \quad (8)$$

where λ is expressed in $\text{W m}^{-1} \cdot \text{K}$, T is the absolute temperature, $k_B = 8.6144 \times 10^{-5}$ is Boltzmann's constant (eV/K), n is a constant, usually 2, $\frac{5}{2}$ or 3, $C = 4.715 \times 10^9$ and $W = 1.41$ is related to the energy gap between conduction and valence bands. More complex dependencies of the temperature have been proposed more recently (IAEA 1997).

Besides temperature and composition, the porosity is an important factor affecting the overall thermal conductivity of a ceramic such as UO_2 . Pores, which are generally filled with gas, poorly conduct the heat and thus act as thermal barriers. Many formulas have been suggested to correct for this effect, mainly assuming that in highly dense materials the pores have a spherical shape, which is indeed the case for sintered UO_2 . One of the most common expressions is the Maxwell–Eucken correction:

$$\lambda = \lambda_0 \frac{1 - P}{1 + \beta P} \quad (9)$$

Here λ_0 is the thermal conductivity of the fully (100%) dense material, P is the porosity, and β is a constant, which is unity for perfect spherical pores. For complex pore shapes, other corrections are needed.

Another popular correction factor is derived from the Loeb correction:

$$\lambda = \lambda_0(1 - \alpha P) \quad (10)$$

where $\alpha = 1.7$ –3.

The thermal conductivity of stoichiometric UO_2 has been measured by many authors and these measurements were evaluated by an IAEA expert group (IAEA 2006). The recommended equation for 95% dense material is

$$\lambda = \frac{100}{7.5408 + 17.692t + 3.6142t^2} + \frac{6400}{t^{5/2}} \exp\left(\frac{-16.35}{t}\right) \quad (11)$$

where λ is the thermal conductivity in $\text{W} \cdot \text{m}^{-1} \cdot \text{K}^{-1}$, and $t = T/1,000$ in Kelvin.

3.2.2 Mixed Oxides

The substitution of Pu^{4+} or Gd^{3+} ions in the UO_2 lattice will substantially affect the thermal conductivity. These ions act as phonon-scattering centers in the crystal lattice, as a result of which the thermal conductivity of $(\text{U,Pu})\text{O}_2$ or $(\text{U,Gd})\text{O}_2$ will be lower than that of pure UO_2 . For these solid solutions Eq. 7 can be changed to

$$\lambda = \frac{1}{A_0 + A_1(x) + BT} \quad (12)$$

where the parameter A_0 describes the temperature independent phonon scattering in the pure compound. The parameter $A_1(x)$ represents the influence of substitution or non-stoichiometry

on the temperature independent phonon scattering and x represents the amount of non-stoichiometry or substitution. The parameter B is less sensitive to substitutions or other scattering centers.

The thermal conductivity of solid solutions can be described adequately by the theory developed by Ambegaokar (1959) and Abeles (1963), as discussed by Gibby (1971) and Fukushima et al. (1986). The parameter $A_1(x)$ in (12) can be represented by

$$A_1(x) = \frac{\pi^2 V \Theta}{3v^2 h} \Gamma \quad (13)$$

where V is the average atomic volume, Θ is the Debye temperature, v is the average phonon velocity, h is Planck's constant. Γ is the scattering cross section parameter of the phonon by the impurity type. Γ is given by

$$\Gamma = x(1-x) \left(\frac{M_1 - M_2}{(1-x)M_1 + xM_2} \right)^2 + \varepsilon x(1-x) \left(\frac{r_1 - r_2}{(1-x)Mr_1 + xr_2} \right)^2 \quad (14)$$

where x is the mole fraction of impurity atoms, M_1 is the mass of the host ion, M_2 is the mass of the substituted ion, r_1 is the ionic radius of the host atom, and r_2 is the ionic radius of the impurity atom. ε is a parameter that represents the strain generated in the lattice and is assumed to be about 100, which is obtained from an analysis of various solid solutions by Fukushima et al. (1986).

Gibby (1971) systematically measured the effect of the Pu content on the thermal conductivity of (U,Pu)O₂ solid solutions up to 30 mol% PuO₂, observing a small but systematic decrease with increasing PuO₂ content. This could be explained by the fact that the Pu⁴⁺ ions substitute on the uranium positions of the UO₂ lattice where they act as phonon-scattering centers, in line with theory. However, Schmidt (1970) found a different dependence on the PuO₂ content with a peak at about 15 mol% in the thermal conductivity, particularly evident at low temperatures. Beauvy (1992) reported similar results, and attributed this to differences in the defect cluster concentrations below and above 12.5 mol% PuO₂. Clearly, further studies are needed as also the strong variation of the thermal conductivity close to O/M = 2.00 (see below) might have affected the results, as well as auto-irradiation effects.

Duriez et al. (2000) made systematic measurements of the thermal conductivity of (U,Pu)O₂ mixed oxide fuel, for average Pu concentrations from 3 to 15 wt% and in the temperature range 700–2,300 K. They used both homogeneous samples and industrial MIMAS samples. The thermal conductivity was found to be significantly lower than that of the UO₂, although no dependence on the Pu concentration was found, neither was a difference between the homogeneous and MIMAS samples observed. Similar to the results of Schmidt, a clear decrease of the thermal conductivity as a function of the O/M ratio was observed. Their results expressed for 95% TD in this concentration range were represented by the equation

$$\lambda = \frac{1}{A(x) + B(x)(T/K)} + \frac{C}{(T/K)^2} \exp \frac{-D}{(T/K)} \quad (15)$$

with $A(x) = 2.85x + 0.035 \text{ m K W}^{-1}$, $B(x) = (2.86 - 7.15x)10^{-4} \text{ m W}^{-1}$, $C = 1.689 \cdot 10^9 \text{ W K m}^{-1}$, and $D = 13,520 \text{ K}$. However, Carbajo et al. (2001) argued that this equation does not reproduce

■ Figure 6

The thermal conductivity of $(U_{0.8}Pu_{0.2})O_{2\pm x}$ for various values of x ; after Schmidt (1971)

the high-temperature data ($>2,000$ K) correctly and suggested a combination of the results of Duriez et al. (2000) and Ronchi et al. (1999):

$$\lambda = \frac{1}{A(x) + B(x)(T/K)} + \frac{6,400}{t^{5/2}} \exp\left(\frac{-16.35}{t}\right) \quad (16)$$

Schmidt (1971) studied the effect of O/M ratio on the thermal conductivity of $(U_{0.8}Pu_{0.2})O_{2-x}$ in the temperature range 373–2,073 K, observing a strong decrease as a function of x , particularly at the lowest temperatures (● Fig. 6), which is due to the fact that Pu^{3+} and oxygen vacancies act as scattering centers. Schmidt also studied the $(U_{0.8}Pu_{0.2})O_{2+x}$ (see Mattys (1968)), revealing as similar trend as for $UO_{2\pm x}$, that is, the thermal conductivity decreases for positive as well as negative values of x , though slightly asymmetric around O/M = 2.00.

The presence of Gd^{3+} ions in the UO_2 lattice causes local distortion, lattice strain, and an increase of oxygen defects (vacancies). This has an impact on the phonon–lattice and phonon–phonon interactions, leading to a decrease of the thermal conductivity of $(U,Gd)O_{2-x}$. Following the recommendation by an IAEA expert group (IAEA 2006), the recommended thermal conductivity equation for $(U,Gd)O_{2-x}$ (95% TD) is that by Ishimoto et al. (1994), valid for the temperature range 300–3,000 K:

$$\lambda = \frac{\lambda_0}{x} \arctan(x) + 3.94 \times 10^{-11} (T/K)^3 \quad (17)$$

$$x = 3.31 \exp(-7.61 \times 10^{-4} (T/K)) \sqrt{\gamma \lambda_0} \quad (18)$$

where γ is the Gd_2O_3 content, and λ_0 is the thermal conductivity of point defect free UO_2 :

$$\lambda_0 = \frac{1}{0.0245 + 2.46 \times 10^{-4} (T/K)} \quad (19)$$

3.2.3 Effects of Irradiation

The thermal conductivity of nuclear fuel decreases with burnup. The decrease is mainly caused by the buildup of fission product atoms and point defects resulting from radiation damage in the UO_2 lattice, both of which act as scattering centers for phonons. Thermal annealing of the spent fuel results in the recovery of the thermal conductivity (Walker et al. 2006). This occurs in two distinct steps. The first step occurs in the temperature range 800–1,000 K (527–727°C) and is associated with the removal of point defects produced by out-of-pile radiation damage. The second step occurs in the temperature range 1,150–1,400 K (877–1,127°C) and is attributed to further annealing of self-irradiation, the onset of annihilation of in-pile radiation damage and the removal of fission product atoms in solid solution in the fuel matrix to form voids and precipitates. Thermal annealing at temperatures below 800 K (527°C) results in slight recovery of the thermal conductivity amounting to less than 10% of the value for the irradiated fuel. This recovery is due to the partial healing of point defects created by self-irradiation in the time interval between discharge of the spent fuel from the reactor and the measurement of the thermal diffusivity. The bulk of the damage created during this time is removed in the first recovery step.

As discussed above, the thermal conductivity of nuclear fuel degrades continuously during irradiation as a result of fission product accumulation and radiation damage. In-pile experiments with instrumented fuel rods (centerline thermocouples) have revealed this effect for LWR fuel, taking into account supplementary information about the linear power and the fuel-cladding gap conductance. Based on the experiments performed in the Halden boiling water reactor (Wiesenack 1997) the following equation is recommended for the thermal conductivity of irradiated UO_2 :

$$\lambda = \frac{1}{0.1148 + 0.0035bu + 2.47510^{-4} \times (1 - 0.0033bu)(T/K) + 0.0132 \exp(0.00188(T/K))} \quad (20)$$

where bu is burnup in MWd/kgU . This correlation is based on a burnup correction to the MATPRO thermal conductivity data for unirradiated UO_2 (Hagman and Reymann 1979).

The thermal conductivity degradation has also been studied directly by out-of-pile experiments. Ronchi et al. (2004) studied the thermal conductivity of irradiated UO_2 up to 92 MWd/kgHM and different in-pile temperatures. By systematic studies of the thermal conductivity of samples irradiated at different burnup and temperature using thermal annealing cycles, these authors established the complex thermal conductivity dependence (► Fig. 7). Ronchi et al. (2004) proposed a thermal conductivity expression based on the classical phonon heat transport equation (Eq. 7) with coefficients A and B depending on the irradiation temperature T_{irr} (700–1,450 K), the maximum temperature reached during annealing T_{ann} (700–1,450 K) following irradiation at T_{irr} , and the local burnup bu (0–100 MWd/kgHM):

$$\lambda = \frac{1}{A(T_{irr}, T_{ann}, bu) + B(T_{irr}, T_{ann}, bu)T} \quad (21)$$

Here T is the instant application temperature (300–1,500 K), which for in-pile applications $T = T_{irr} = T_{ann}$. The set of relevant equations to use this expression is summarized in ► Table 1.

There is limited information on the thermal conductivity of irradiated MOX in the open literature. Cozzo et al. (2010) reported the results for homogeneous SBR MOX of 35 MWd/kgHM

■ Figure 7

The thermal conductivity of irradiated UO_2 fuel (Ronchi et al. 2004) © Elsevier, 2004, reprinted with permission

obtained from out of pile studies. The results agree well with those for irradiated UO_2 by Ronchi et al. (2004) for the same burnup. This can be explained by the fact that the composition of UO_2 and low Pu content MOX fuel converge during irradiation, the UO_2 producing Pu and the MOX consuming Pu, both accumulating fission products and radiation damage in an homogeneous way.

3.3 Heat Capacity

The heat capacity of UO_2 has been evaluated by many authors and various expressions have been suggested. The difficulty is that the heat capacity of UO_2 shows an anomalous behavior above 2,000 K as a result of Frenkel pair formation on the oxygen lattice and excitation of the electronic levels of U^{4+} . The recommendation by Fink (2000) for the temperature range 298.15 K < T < 3,120 K is generally accepted, and can be represented by

$$C_p(T)/(\text{J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}) = 52.1743 + 87.951t - 84.241t^2 + 31.542t^3 - 2.6334t^4 - 0.71391t^{-2} \quad (22)$$

■ Table 1

Dependencies of the parameters of Eq. 21

$A(T_{irr}, T_{ann}, bu)/m \cdot W^{-1} \cdot K^{-1}$	$= 0.046 + \Gamma(bu, GLS) + \delta A^{a,b}$
$\Gamma(bu, GLS)$	$= 9.02 \times 10^{-4} bu GLS + 1.74 \times 10^{-3} bu + 7.51 \times 10^{-3} a$
δA	$= \delta A_{self}(T_m, bu) + \delta A_{EOL}(T_m, bu)^c$
$\delta A_{EOL}/m \cdot K \cdot W^{-1}$	$= \frac{bu}{850} \left[\left(1 + \exp\left(\frac{T_m - 950}{25}\right) \right)^{-1} + \left(1 + \exp\left(\frac{T_m - 1,300}{35}\right) \right)^{-1} - 0.0525 \right]$
$\delta A_{self}(T_{ann}, bu)/m \cdot K \cdot W^{-1}$	$= 0.02F(bu)$ for $T_{ann} < 900$ K $= 0.02F(bu) \frac{1,450 - T_{ann}}{1,450 - 900}$ for $900 < T_{ann} < 1,450$ K $= 0$ for $T_{ann} > 1,450$ K
$B(T_{irr}, T_{ann}, bu)/m \cdot W^{-1}$	$= B_0 + (B_1 - B_0) + \frac{6.5 \times 10^{-5} - \delta B}{6.5 \times 10^{-5}}$
$B_0/m \cdot W^{-1}$	$= 1.65 \times 10^{-6} bu + 2.55 \times 10^{-4} + 3.6 \times 10^{-5} IRIM^d$
B_1	$= 4.2 \times 10^{-7} bu + 2.75 \times 10^{-4}$
δB	$= F(bu) \delta B_{EOL}(T_m, bu)$
$\delta B_{EOL}/m \cdot W^{-1}$	$= \frac{bu}{34} \left[\left(4.0 \times 10^{-5} \left(1 + \exp\left(\frac{T_m - 950}{25}\right) \right)^{-1} \right. \right.$ $\left. \left. + 2.5 \times 10^{-5} \left(1 + \exp\left(\frac{T_m - 1,300}{35}\right) \right)^{-1} \right] \right]$
$GLS(bu, T_{ann}, T_{irr})$	$= \frac{1 - 0.9 \left[1 + \exp\left(\frac{T_{irr} - 950}{30}\right) \right]^{-1} \left[1 + \exp\left(\frac{73 - bu}{2}\right) \right]^{-1}}{\left[1 + \exp\left(\frac{T_{irr} - 1,350}{200}\right) \right] \left[1 + \exp\left(\frac{T_{ann} - 1,350}{200}\right) \right]}$
$IRIM$	$= \left[1 + \exp\left(\frac{T_{irr} - 950}{30}\right) \right]^{-1} \times \left[1 + \exp\left(\frac{73 - bu}{2}\right) \right]^{-1} d$
$F(bu)$	$= \left(1 - \exp\left(\frac{20 - bu}{6}\right) \right)^{-1} - 0.015267$

^a GLS is the fraction of gas in solid defined as the ratio of the gas amount present in dynamical solution to the total produced inventory.

^b Γ is the total scattering coefficient.

^c $T_m = \max(T_{irr}, T_{ann})$.

^d $IRIM$ is the correction associated with the hbs formation.

where $t = T/1,000$ with temperature T in Kelvin. This equation does not reproduce the λ type transition at $(2,670 \pm 30)$ K in heat capacity measurements in the pre-melting range that was observed by Ronchi and coworkers (Hiernaut et al. 1993; Ronchi et al. 1999).

Carbajo et al. (2001) critically evaluated the heat capacity and enthalpy data for $(U,Pu)O_2$ and concluded that the results for the solid phase can be described well by the Neumann–Kopp rule:

$$C_p(T, U_{1-y}Pu_yO_2) = (1 - y)C_p(T, UO_2) + yC_p(T, PuO_2) \quad (23)$$

which is in line with the fact that this solid solution is ideal. Measurements by Duriez et al. (2000) confirmed this conclusion.

The recommended equation for the heat capacity of $(U_{1-y}Gd_y)O_2$ by the IAEA expert group (IAEA 2006) is $(298.15-2,000\text{ K})$:

$$C_p = C_{p0} + \Delta C_p \quad (24)$$

$$C_{p0} = 79.8 + (0.1263y^2 - 0.0073y + 0.0061)(T/K) - (1.68 - 1.48y) \times 10^6 (T/K)^{-2} \quad (25)$$

where ΔC_p is expressed as

$$\Delta C_p = \frac{\Delta H^*}{\sqrt{2}RT^2} \exp\left(\frac{\Delta S^*}{2R}\right) \exp\left(\frac{\Delta H^*}{\sqrt{2}RT}\right) \quad (26)$$

where $\Delta H^* = (-73,880y^3 + 10,190y^2 - 612.13y + 310) \times 10^3 \text{ J}\cdot\text{mol}^{-1}$ is the enthalpy of formation of Frenkel pair formation and $\Delta S^* = 61.969 - 45.564y \text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$ is the entropy of formation of Frenkel pair formation. These Frenkel pairs of oxygen are formed because the substitution of Gd^{3+} on the uranium lattice creates oxygen vacancies on the oxygen sub-lattice. To maintain a nearly stoichiometric composition for $(U,Gd)O_2$, an oxygen interstitial must be formed (together with U^{5+} formation). As discussed in IAEA (2006) the entropy and enthalpy of formation per Frenkel pair thus obtained are higher than the values known from UO_2 , but when extrapolated to zero Gd content, they are in fair agreement with the estimated values for UO_2 .

3.4 Melting Temperature

The melting point of UO_2 has been the subject of many studies. In the most recent reviews (Carbajo et al. 2001; Fink 2000; IAEA 2006) the recommended melting point is $T_{fus} = (3,120 \pm 20) \text{ K}$, the value suggested by Adamson et al. (1985). Recent measurements confirm this value.

The melting temperature of $(U,Pu)O_2$ is strongly dependent on the composition. The UO_2 - PuO_2 phase diagram, as shown in  Fig. 8, indicates that the liquidus and solidus lines steadily decrease with increasing PuO_2 concentration, which can be represented by the following equations (Adamson et al. 1985):

$$T_{\text{solidus}}/K = 3120 - 655.3x + 336.4x^2 - 99.9x^3 \quad (27)$$

$$T_{\text{liquidus}}/K = 3120 - 388.1x - 30.4x^2 \quad (28)$$

These recommendations are based on the results of Aitken and Evans (1968) and Lyon and Bailey (1967) from the 1960s, among others. However, the recent measurements by Kato et al. (2008) are in disagreement with these results, and suggest a melting point for pure PuO_2 about 200 K higher than the recommended value. Further experiments are required to solve this discrepancy.

The phase diagram of the UO_2 - Gd_2O_3 system has been studied by Beals et al. (1969) and more recently by Kang et al. (2007). Their results for the liquidus are close but those for the solidus differ significantly. The results by Kang et al. (2007) can be represented by

$$T_{\text{solidus}}/K = 3120 - 48.01x + 1.31x^2 \quad (29)$$

$$T_{\text{liquidus}}/K = 3120 - 8.0x \quad (30)$$

where x is the weight fraction of Gd_2O_3 .

■ Figure 8

The pseudobinary phase diagram $\text{UO}_2\text{--PuO}_2$. The circles give the experimental data by (Lyon 1967), the triangles by (Aitken and Evans 1968), and the squares by (Kato et al. 2008). The solid lines represent the recommended liquidus and solidus by (Adamson et al. 1985), the broken line represents the ideal liquidus and solidus based on the results of Lyon and Baily, and the dotted line represents the liquidus and solidus suggested by Kato et al.

The effect of irradiation on the melting temperature of UO_2 has been studied by several authors. Christensen (1962) reported an increase of more than 100 K for the melting point of UO_2 irradiated to 1.12×10^{19} fissions/ cm^3 . At higher exposures, he observed a decrease of 40 K at approximately 2×10^{19} fission/ cm^3 and of 130 K at approximately 2.7×10^{19} fissions/ cm^3 . Subsequent work by Christensen et al. (1964) showed a nearly linear decrease of approximately 10 K per 10^{19} fissions/ cm^3 in melting temperature with exposure between 6.3×10^{19} and 1.6×10^{21} fissions/ cm^3 . Bates (1970), repeating the work of Christensen, found no difference between the melting temperatures of nonirradiated and UO_2 irradiated up to 1.9×10^{20} fissions/ cm^3 . This was further confirmed by measurements by Yamanouchi et al. (1988) for irradiated UO_2 and $\text{UO}_2\text{--}2\text{wt}\%\text{Gd}_2\text{O}_3$ fuel with burnup up to 30 MWd/kgHM.

4 Properties of Cladding Materials for LWRs Fuel

4.1 Composition

The selection of zirconium as main component for cladding material in light water reactors was made on the basis of its mechanical strength, its low thermal neutron capture cross section, and its high corrosion resistance in high-temperature water. Several alloying elements have been added for different reasons:

- **Oxygen:** The addition of the soluble alloying element oxygen raises the yield strength of zirconium, thanks to solution strengthening or its interaction with mobile dislocations. The addition of approximately 1,000 ppm doubles the yield strength at room temperature from 150 to 300 MPa.

■ **Table 2**

Nominal composition of commercial Zr-based alloys for claddings

Alloy	Sn (wt.%)	Nb (wt.%)	O (wt.%)	Fe (wt.%)	Cr (wt.%)	Ni (wt.%)	Zr
Zry 2	1.45	–	0.125	0.14	0.10	0.06	Balance
Zry 4	1.45	–	0.125	0.21	0.10	–	Balance
Zirlo	1.1	1.1	0.120	0.1	–	–	Balance
M5	–	1.0	0.135	0.038	–	–	Balance
E110	–	1.0	0.06	0.009	–	–	Balance

- **Tin:** The solution of Sn aims at promoting the corrosion resistance of the cladding material and is typically on the order of 1.2–1.7% .
- **Iron, Chromium, and Nickel:** These elements are mainly soluble in the high temperature body-centered cubic BCC β phase. In the low-temperature hexagonal closed packed HCP α phase, they form intermetallic precipitates such as $\text{Zr}(\text{Cr},\text{Fe})_2$ and $\text{Zr}_2(\text{Ni},\text{Fe})$ because of their maximum solubility limit being 20 and 200 ppm for Fe and Cr in the α phase respectively. The size and stability of the precipitates strongly affects the corrosion rate (cf. ➤ [Sect. 4.5](#)).
- **Niobium:** Niobium stabilizes the β phase and improves several properties related to irradiation damage such as corrosion and growth (cf. ➤ [Sect. 4.5](#)). Given the reduced corrosion of zirconium–niobium alloys in comparison with the zirconium–tin alloys during normal operation, niobium has been added in recent years to alloys used in Western type PWRs. In advanced cladding materials, with a typical concentration of 1%, niobium forms intermetallic particles of cubic $[(\text{Zr},\text{Nb})_4\text{Fe}_2]$ and hexagonal $[\text{Zr}(\text{Nb},\text{Fe})_2]$ structure. This is in contrast to tin that is completely soluble in zirconium.

The chemical composition of the main cladding materials applied in the nuclear industry is listed in ➤ [Table 2](#). Zircaloy-2 (Zry-2) cladding is used in boiling water reactors. In Western type pressurized water reactors Zircaloy-4 (Zry-4), ZIRLO, and M5 are used, whereas in Russian-type WWERs the alloy E110 is applied.

The density of the zirconium alloy is about $6,550 \text{ kg/m}^3$ at room temperature, and has a melting temperature of about 2,100 K (➤ [Figs. 9](#) and ➤ [10](#)).

4.2 Microstructure

The lattice structure of pure zirconium at room temperature is the HCP α phase, with a lattice parameter of 0.323 nm in the basal plane and 0.515 nm along the c -axis. Above 865°C , pure zirconium transforms to the BCC β phase (➤ [Fig. 9](#)). The phase transformation from α to β and vice versa affects the strength of the cladding during accidental conditions such as loss-of-coolant accidents. The transformation is influenced by the composition (e.g., oxygen and niobium content) as well as the microstructure resulting from the fabrication process, and the temperature rate because of the diffusion processes involved. Specific correlations are therefore proposed for different cladding materials. As an example, Forgeron et al. (2000) provide a dynamic model

■ Figure 9

The Zr–Nb phase diagram; after Jerlerud Pérez and Massih (2007) ©Elsevier, 2007, reprinted with permission

for the fraction of the β phase as a function of the heating or cooling rate for Zircaloy-4:

$$\frac{d\beta}{dt} = K(T) \cdot \beta \cdot (1 - \beta) \quad (31)$$

where $K(T)$ is an empirical formula of the temperature:

$$K = \pm |T - T_{eq}| \cdot \exp(c_1 + c_2 \cdot |T - T_{eq}|) \quad (32)$$

■ **Table 3**

Examples of Kearns factors for various textures of Zircaloy

	f_r	f_θ	f_z
Isotropic	$\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{3}$
Purely radial	1	0	0
Stress relieved annealed	0.59	0.32	0.09
Recrystallized	0.54	0.32	0.14

where $c_1 = -5.725$ and $c_2 = 0.05$, and T_{eq} represents the thermodynamic equilibrium temperature between the α and β phase, and is the inverse function of the equilibrium curve:

$$\beta_{eq} = 1 - \exp\left(-\left[k(T - T_0)^z\right]\right) \quad (33)$$

where β_{eq} represents the equilibrium fraction of the β phase, T_0 is the incubation temperature (1,085.15 K), and $k = 1 / (T_{\beta_{eq}=0.632} - T_0)$, where $T_{\beta_{eq}=0.632} = 1,170.15$ K and $z = 2.1$.

The fabrication process of Zircaloy results in an anisotropic polycrystalline material. The basic deformation mechanisms of HCP Zry consist of slip and twinning, depending on the relative orientation of the grain with respect to the stress field. The mechanical processing during fabrication results in interactions between both the slip and the twin systems. Consequently, the slip systems tend to align the basal planes parallel to the direction of the main deformation. The cold-rolled cladding material has a texture or preferred crystallographic orientation that is characterized by a majority of grains having their c -axis tilted 30–40° away from the normal of the clad surface toward the tangential direction.

The cold work (rolling) during the fabrication process therefore induces a texture-induced anisotropy. The anisotropy is determined by the degree of cold work (area reduction), but also by temperature and hold-time of the heat treatment. The cladding texture is generally characterized by means of Kearns texture factors f_r , f_θ , f_z , corresponding to resolved fractions of basal poles of the c -direction in the various cladding directions, as illustrated by a few examples in ► [Table 3](#). These factors are used in the expressions for the irradiation-induced growth (cf. ► [Sect. 4.5](#)).

Unless specifically mentioned otherwise the following sections will provide information and properties about standard cladding materials Zircaloy-2 and Zircaloy-4. Most of those properties can be applied to other zirconium-based alloys such as ZIRLO and M5 as a first approximation, except for

- Thermal properties: specific heat, thermal expansion
- Mechanical properties: density, elastic constants, yield stress, creep
- Irradiation properties: corrosion, irradiation growth

As a matter of fact, for the advanced cladding materials some of the properties are not available in the open literature.

4.3 Thermal Properties

4.3.1 Linear Thermal Expansion

The linear thermal expansion coefficient of the Zircaloy cladding material is smaller than that of the oxide fuel, contributing to the closure of the fuel-to-clad gap during operation. Thermal expansion of Zircaloy cladding is more pronounced in the c -direction, although the anisotropy reduces with temperature. For single crystals with a temperature between 300 and 1,083 K (MATPRO 1993)

$$\varepsilon_{11} = 4.95 \times 10^{-6} T - 1.485 \times 10^{-3} \quad (34)$$

$$\varepsilon_{33} = 1.26 \times 10^{-5} T - 3.78 \times 10^{-3} \quad (35)$$

where ε_{11} is the circumferential thermal expansion, ε_{33} is the axial thermal expansion and T is the temperature (K). For temperatures between 1,083 and 1,244 K

$$\varepsilon_{11} = \left[8.76758 + 1.09822 \cos \left(\frac{T - 1,083}{161} \pi \right) \right] \times 10^{-3} \quad (36)$$

$$\varepsilon_{33} = \left[2.77763 + 1.09822 \cos \left(\frac{T - 1,083}{161} \pi \right) \right] \times 10^{-3} \quad (37)$$

where the arguments of the cosines are in radian. For $1,244 \leq T \leq 2,098$ K

$$\varepsilon_{11} = 9.7 \times 10^{-6} T - 1.04 \times 10^{-2} \quad (38)$$

$$\varepsilon_{33} = 9.7 \times 10^{-5} T - 4.4 \times 10^{-3} \quad (39)$$

For $T > 2,098$ K (liquid)

$$\varepsilon_p = \frac{2}{3} \varepsilon_{11} + \frac{1}{3} \varepsilon_{33} + 0.0067 \quad (40)$$

where ε_{11} is the circumferential thermal expansion strain of a single Zircaloy crystal at 2,098 K, ε_{33} is the axial thermal expansion strain of a single Zircaloy crystal at 2,098 K, and ε_p is the thermal expansion of molten Zircaloy. In order to infer the cladding strains on the basis of the strain in a single crystal, it is necessary to perform a volume-weighted averaging over the entire cladding section.

4.3.2 Thermal Conductivity

The thermal conductivity of Zircaloy mainly depends on temperature, rather than crystal orientation, and minor composition differences such as those between Zry-2 and Zry-4. Texture may have an effect in the α phase temperature region, in which Zircaloy is crystallized in a hexagonal, close-packed configuration. Indeed, there may be some difference in the thermal conductivity along the prismatic and basal directions. At higher temperatures, the material is body-centered

cubic and will not exhibit texture effects. In any case, contributions to the thermal conductivity due to texture are well within the scatter of the experimental data.

According to the MATPRO library (1981, 1990), the following correlations are recommended for the thermal conductivity (W/m·K) of both Zircaloy-2 and Zircaloy-4 when $300 \text{ K} < T < 2,098 \text{ K}$

$$\lambda = 7.51 + 2.09 \times 10^{-2} T - 1.45 \times 10^{-5} T^2 + 7.67 \times 10^{-9} T^3 \quad (41)$$

and when $T \geq 2,098 \text{ K}$

$$\lambda = 36 \quad (42)$$

where T is the temperature (K).

4.3.3 Specific Heat Capacity

The specific heat capacity for Zircaloy 2 and Zircaloy 4 at constant pressure ($\text{J}/(\text{g} \cdot \text{K})$) is given by (Zimmerer 1978)

$$c_p = 286 + 9.286 \times 10^{-2} T \quad (43)$$

for $T \leq 800^\circ\text{C}$. When the temperature lies between 800 and 907°C

$$c_p = -3340.512 + 4.626 T \quad (44)$$

and if $907 \leq T \leq 985^\circ\text{C}$

$$c_p = 6611.092 - 6.346 T \quad (45)$$

For temperatures beyond 985°C a constant value of $c_p = 350.282$ is recommended.

For E110 cladding with 1% Nb, applied for instance in Russian-type WWER reactors, Volkov et al. (1989) have published values for $T < 866.5 \text{ K}$

$$c_p = -1.660714 \times 10^{-4} T^2 + 2.866393 \times 10^{-1} T + 2.612246 \times 10^{-2} \quad (46)$$

where c_p is expressed in $\text{J}/(\text{g} \cdot \text{K})$. When $T < 131.3 \text{ K}$

$$c_p = -2.740292 T - 1.989514 \times 10^3 \quad (47)$$

and when $T < 116 \text{ K}$ then

$$c_p = -3.236827 T + 4.174431 \times 10^3 \quad (48)$$

Finally, for β -Zry above $1,168 \text{ K}$, a constant value of $c_p = 393.817 \text{ J}/(\text{g} \cdot \text{K})$ is suggested.

4.3.4 Emissivity

In principle, the total emissivity depends on the surface roughness and oxide thickness. However, a constant value of 0.8 is recommended in the MATPRO library (1981, 1990) and in the review of thermophysical properties for oxidized Zircaloy from the IAEA. In contrast, a constant value of approximately 0.2 is recommended for unoxidized Zircaloy.

4.4 Mechanical Properties

In view of the texture of the Zircaloy, the mechanical properties are generally anisotropic in the α phase, whereas the anisotropy disappears in the β phase.

4.4.1 Elastic Constants

Elastic moduli are required to relate stresses to strains. The elastic moduli are defined by the generalized form of Hooke's law as elements of the fourth rank tensor that relates the second rank stress and strain tensors prior to yielding. In practice, however, cladding is frequently assumed to be an isotropic material. In such a case, only two independent elastic moduli are needed to describe the relation between elastic stress and strain: Young's modulus and the shear modulus.

Cladding elastic moduli are affected primarily by temperature and oxygen content. Fast neutron fluence, cold work, and texture effects should also be included in the models, such as in the MATPRO library, but they are not as important as temperature and oxygen content for typical LWR fuel rod cladding. Therefore, codes often adopt a temperature dependent correlation for the elastic modulus (MPa)

$$E = 1.088 \times 10^3 - 5.475 \times T \quad (49)$$

where the temperature is expressed in degree Celsius and the oxygen concentration resulting from fabrication is in the range of 1,200 to 1,400 ppm. Similarly, the shear modulus is often approximated by a constant value of 0.3 or by a temperature dependent expression

$$G = 4.04 \times 10^3 - 2.168 \times T \quad (50)$$

4.4.2 Plastic Deformation

The plastic deformation in metals takes place by movements of linear lattice defects or dislocations and is controlled by shear stresses. It is therefore made possible and hindered by lattice defects, follows crystallographic planes and preserves the volume. More precisely, plastic deformation through dislocation slip is hindered by clusters of point defects such as alloying elements, oxygen and irradiation damage (or cold work). Furthermore, the second-phase particles formed by alloying elements and hydrides (cf. [Sect. 4.5](#)) also hinder dislocation slip, as well as dislocation pileup, referred to as deformation hardening. These factors thus increase the yield strength and make it dependent on both the composition and fabrication route, that is, it is specific for each cladding type and generally on the order of 550 MPa.

4.5 Irradiation Effects

4.5.1 Irradiation-Induced Growth

Clustering of irradiation-induced point defects caused primarily by fast neutrons can occur in an anisotropic manner. For instance, when all the vacancies form loops that are perpendicular to a plane, while the interstitials form loops parallel to the same plane, the crystal will shrink

and expand (at constant total volume) in the direction parallel to and perpendicular to that plane, respectively. In the Zircaloy cladding, irradiation growth is also due to partitioning of interstitials and vacancies to various sinks that are not isotropically distributed in the material. For Zr single crystals, irradiation growth consists of an expansion along the $\langle a \rangle$ direction and a corresponding contraction along the $\langle c \rangle$ axis. In polycrystalline zircaloy the situation is of course more complex, although on average expansion and contraction also occur along the same directions as in single crystals. Due to the texture caused by the fabrication, however, prism planes are preferentially aligned perpendicular to the axial direction. Irradiation growth therefore causes axial elongation. Since the irradiation growth is influenced by microstructural variables such as the amount of cold work, residual stresses, tubing texture, and composition (alloying additions) there are various correlations available. One that is generally applicable for both standard Zircaloy-2 and Zircaloy-4 can be found in MATPRO (1981, 1990):

$$\frac{\Delta L}{L} = a [\exp(240.8/T)] (\phi t)^{1/2} (1 - 3f_z)(1 + 2CW) \quad (51)$$

where $\frac{\Delta L}{L}$ represents the fractional change in length due to irradiation growth, $a = 1.407 \times 10^{-16} (\text{n/m}^2)^{1/2}$, T is the cladding temperature (K), Φt corresponds to the fast neutron fluence (n/m^2) ($E > 1 \text{ MeV}$), f_z is the texture factor for the tubing axis, that is, the effective fraction of grains aligned with their $\langle 0001 \rangle$ axis parallel to the tubing axis, and CW designates the fraction of cross-sectional area reduction due to cold work.

In normal operating conditions, the change in length of fuel rods due to irradiation growth is small. However, it can be a significant fraction of the clearance between the rod and the top and bottom assembly nozzles. Contact with those nozzles can cause rods bowing and possibly failure at points where rods contact each other.

In addition to normal growth as expressed above, a breakaway phenomena has been observed after a fluence of about $3 \times 10^{25} \text{ n/m}^2$, which has been linked to the development of $\langle c \rangle$ component dislocations. Nevertheless, in recrystallized ternary alloy of Zr, Nb, and O referred to as M5TM, very few $\langle c \rangle$ component basal loops have been observed so that no sign of accelerated growth regime is expected for fuel burnup values of PWR fuel rods up to 70 GWd/t.

4.5.2 Irradiation-Induced Hardening

Due to the high concentration of point defects and dislocations produced by the neutron irradiation, dislocation slip is inhibited, hence the yield strength increases. The increase in yield strength is associated with a reduction in ductility and affects the total elongation from 20% to a few percent. Nevertheless, both the yield strength and the ultimate tensile stress saturate beyond a fluence of about $5 \times 10^{24} \text{ n/m}^2$ in both stress relieved and recrystallized Zircaloys. Saturation is caused by the overlapping absorption volumes for interstitials and vacancies by an increasing loop concentration.

4.5.3 Irradiation-Induced Creep

Generally, the creep of materials comprises three successive domains:

- The primary creep where the specimen begins to deform relatively quickly whereupon the creep rate decreases with time,

- The secondary creep that is characterized by a constant strain rate,
- The tertiary creep that corresponds to an increase of the strain rate and finally leads to the failure of the material.

At high temperature, there are two kinds of creep mechanisms, namely creep controlled by dislocation movements, and creep controlled by diffusion. For the first kind, when the plastic flow is mainly ensured by the thermally activated movement of dislocations, creep follows a power law of the Norton type:

$$\dot{\epsilon} = A \cdot \sigma^n \cdot \exp\left(-\frac{\Delta E}{RT}\right) \quad (52)$$

where $\dot{\epsilon}$ represents the effective strain rate, σ is the effective stress, A and n are constants, ΔE is the molar activation enthalpy, R the gas constant, and T is the absolute temperature.

When creep is controlled by core diffusion (Nabarro–Herring creep), the power-law does not apply anymore and the strain rate is a function of the applied stress, the vacancies diffusion coefficient D , and the grain size d :

$$\dot{\epsilon} = K \cdot \frac{\sigma D}{d^2} \cdot \exp\left(-\frac{\Delta E}{RT}\right) \quad (53)$$

where K is a constant.

During normal operating conditions in a reactor, slow deformation under an external stress experienced by the cladding material under irradiation can occur due to creep that is promoted by the neutron flux. The total creep strain is therefore dependent on the temperature, stress level, and neutron flux. For practical purposes the cladding creep strain in fuel performance codes generally consists of two components. The first corresponds to high-temperature creep and depends only on temperature and stress, while the second component is irradiation induced and only depends on the stress and the neutron flux:

$$\dot{\epsilon} = A \cdot \sigma^n \cdot \exp\left(-\frac{Q}{k \cdot T}\right) + B \cdot \sigma^m \cdot \phi^n \quad (54)$$

The usual values of those exponents are $m = 0.6$ to 1 , and n close to 1 , while the activation energy Q is in the range of 0.05 to 0.16 eV per atom. It is assumed that irradiation creep deformation occurs by dislocation climb and glide, where climb is controlled by the absorption of point defects at dislocations.

4.5.4 Corrosion and Hydrogen Pickup

Zirconium alloys are very corrosion resistant in general. Under stringent conditions (300°C , $7\text{--}15$ MPa) in light water reactors, however, corrosion determines the design life of fuel rods and other components. A number of different corrosion morphologies have been observed under irradiation in power reactors. First of all, in PWRs, usually a *uniform oxide growth* is observed, provided that enough dissolved hydrogen is present to suppress water radiolysis. When these films exceed approximately $100\text{ }\mu\text{m}$, oxide delamination and spalling can occur. A second distinct corrosion morphology is *nodular corrosion* and has been observed in BWRs, where water radiolysis and boiling allow oxygen to accumulate in water. Rigorous control of the second-phase particle sizes in Zry-2 has largely eliminated the nodular corrosion problem, although

at the expense of an enhanced uniform oxide growth, and sometimes with late development of nodules. A third and last corrosion morphology was observed in BWRs as well and was referred to as *shadow corrosion* because it appeared when *shadows* of the stainless steel control-blade handles were observed on the outsides of fuel boxes, or when small patches of thicker oxide appeared at contact points between fuel cladding and spacer grids from stainless steel or nickel alloys due to a galvanic effect.

In general, cladding oxidation during normal LWR operation occurs in two stages. At the beginning, a protective black oxide film develops. The corrosion layer is dense and contains mostly tetragonal zirconium, an allotropic form that is stable at high pressure and temperature.

The oxidation of zirconium alloys by water in the temperature range from 573 to 673 K proceeds by the migration of oxygen vacancies from the oxide metal interface through the oxide layer along grain boundaries to the oxide coolant surface (and the accompanying migration of oxygen as O^{2-} in the opposite direction). The vacancies at the metal oxide surface are generated by the large chemical affinity of zirconium for oxygen. Although the rate of oxidation is controlled in part by vacancy migration, the process of oxygen transfer from coolant to metal is not complete until the vacancy is annihilated by an oxygen ion at the oxide coolant surface. It is thus reasonable to expect the complex combination of both bulk oxide properties effects and surface or coolant chemistry to affect the initial corrosion rate. Since there is presently no consensus about the detailed mechanisms modelers have recourse to an empirical relation to describe the time dependency of zircaloy oxidation (MATPRO 1981, 1990, 1993):

$$\dot{\epsilon}_{ox} = k \cdot t^n \exp\left(-\frac{Q}{T}\right) \quad (55)$$

where ϵ_{ox} represents the oxidation thickness expressed either as a size (μm) or a weight gain (mg/dm^2), k is the pre-exponential factor, T is the absolute temperature, and Q the oxidation activation energy.

If the low-temperature oxidation would have been controlled by diffusion alone in the protective layer, the oxygen concentration would obey Fick's law:

$$J = -D \frac{\partial O}{\partial x} \quad (56)$$

where J represents the flux of oxygen atoms expressed in atoms per unit of surface and time, D is the diffusion coefficient expressed in surface per second, O corresponds to the oxygen concentration expressed in atoms per unit volume, and x is the distance in the direction perpendicular to the oxide surface. Assuming that O is fixed on both sides of the protective layer, corresponding to the saturation concentration in the metal phase (O_m) on one side and to the oxygen concentration in the coolant (O_{cool}) on the other side, the oxide growth rate can be expressed as

$$\frac{dw_{ox}}{dt} = -D \frac{O_m - O_{cool}}{O_{av} w_{ox}} \quad (57)$$

whereby the oxide growth rate is obtained by dividing the flux of oxygen atoms arriving at the metal oxide interface by the average oxygen concentration in the oxide layer (O_{av}). As a consequence, Eq. (57) indicates that the oxide layer growth rate becomes inversely proportional with the oxide thickness when diffusion controls the oxygen migration in the protective layer, leading to a parabolic time dependence: $n = -\frac{1}{2}$. However, it is generally observed

that the initial oxidation rate is inversely proportional to the square of the oxide thickness, corresponding to $n = -\frac{2}{3}$. This has been interpreted (MATPRO 1993) as being due to the short lifetime of the oxygen vacancies during their migration toward the coolant with respect to the time to diffuse across the protective layer. Indeed, for an infinite lifetime, the oxygen vacancy flux would obey Eq. (56), whereas for a short lifetime the flux of oxygen vacancies arriving at the coolant would be inversely proportional to the time required to arrive at the oxide coolant interface. This duration is proportional to the square of the average diffusion distance, hence the oxygen flux or the oxide growth rate in Eq. (57) would become inversely proportional with the square of the oxide thickness, resulting in $n = -\frac{2}{3}$. Nevertheless, the actual mechanism reducing the lifetime of the oxygen vacancies remains unexplained.

After a certain oxidation time, commonly referred to as the transition time, the second stage of the corrosion starts. This occurs when the compressive stresses in the oxide layer cannot be compensated by the tensile stresses in the metallic substrate and plastic yield in the metal limits the compression in the oxide. The tetragonal phase becomes unstable and the oxide transforms to a monoclinic form. An interconnected porosity develops, creating shortcuts for oxidizing water. Once this transformation occurred, only a portion of the oxide layer remains protective and the corrosion is controlled by diffusion through the dense protective layer only. Since the thickness of this layer remains almost constant (in the order of 1 μm) the corrosion rate is constant for this transition, hence $n = 1$.

Careful out of pile experiments have been used to infer the constants in the oxidation rate equation in the two phases van der Linde (1965):

$$\dot{w} = 27.1 \times 10^3 \cdot t^{\frac{1}{3}} \exp\left(-\frac{5,220}{T}\right) \quad (58)$$

for pre-transition oxidation, where the temperature T is expressed in Kelvin and the oxidation rate in weight gain (mg/dm^2). After the transition the oxidation rate can be expressed as

$$\dot{w} = 23.0 \times 10^8 \cdot t \exp\left(-\frac{14,400}{T}\right) \quad (59)$$

In general, the transition is a function of temperature and oxide layer thickness. Considering that the oxidation is expressed in weight gain (mg/dm^2), the weight gain at transition is given by (MATPRO 1981, 1990)

$$w_{tr} = 123 \cdot \exp\left(-\frac{790}{T}\right). \quad (60)$$

The above-mentioned equations for Zircaloy cannot be applied directly to predict in-pile oxidation. There is a need to apply an enhancement factor A : $\hat{w}_{tr} = A \cdot w_{tr}$ where $\hat{w}_{tr}$ is the corrected value. The correction factor has been ascribed to either an increased supply of oxygen ions, or to irradiation damage in the oxide layer. Since no definite answer could be provided, the enhancement factor is fitted to experimental data. For BWR reactors, the enhancement factor proposed between 500 and 673 K is (MATPRO 1993)

$$A = 4.84 \times 10^5 \exp\left(-1.945 \times 10^{-2} T_c\right) \quad (61)$$

where T_c is the oxide outer surface temperature (K). For PWRs, the equation for A in the same temperature range reads

$$A = 1.203 \times 10^2 \exp(-7.118 \times 10^{-3} T_c) \quad (62)$$

It should be underlined that the rate enhancement factor A does not result in a linear change in the oxide thickness, even though the post-transition oxidation thickness varies linearly with time. This is due to the effect of the enhancement factor on the pretransition oxidation rate, which is nonlinear. It should also be underlined that the scatter in experimental data for oxidation of individual rods is considerable, with the maximum measured value deviating by as much as a factor two from the average value. These differences are caused by temperature variations and/or local variations in coolant quality or chemistry due to nucleate boiling and contaminants for instance.

Since the ZrO_2 layer is much more brittle than the underlying Zircaloy metal, and contains micro-cracks and pores, cracks will initiate in a cladding subjected to a tensile stress during a pellet-clad mechanical interaction. Since stress concentration increases with crack length, the localization effect increases with oxide thickness.

Another important consequence of cladding oxidation is hydrogen production:

Hydrogen is also produced by radiolysis of water.

A fraction of the hydrogen ions penetrates the oxide and diffuses to the metallic part. When the hydrogen content in the metal exceeds the solubility limit, it precipitates and forms brittle hydrides.

The latter form as single platelets or as elongated groups of platelets. The degree of cladding embrittlement in hydrided zirconium alloys depends on both the hydride morphology and its relative orientation to the stress field. A crack usually propagates through hydrides perpendicular to the hydride layer. It is relevant for high burnup fuel, and in particular for its resistance during ramps and accidents such as reactivity-initiated accidents (RIA).

In the case of niobium-containing cladding materials (e.g., M5 and ZIRLO), a uniform distribution of α and β grains is obtained after fabrication. The β grains are metastable and decompose on aging into a mixture of α -Zr and β -Nb. The α -Zr phase itself is supersaturated in Nb and an irradiation-induced precipitation occurs, which is believed to improve corrosion resistance, and therefore also inhibit the hydrogen uptake. In comparison with Zircaloy-4, the corrosion resistance of the M5 alloy (Bossis et al. 2006) is improved by a factor 3 to 4, and a hydrogen content reduction by a factor 5 to 6 at burnups up to 60 GWd/t. The low tin Zircaloy-4 reaches a corrosion layer thickness of about 90 μm , whereas for M5 this layer remains below 20 μm after irradiation in a PWR to 70 GWd/t. No hydride precipitation is therefore expected in M5 during service.

4.6 High-Temperature Effects

During a loss-of-coolant accident (cf. ► Sect. 6.4) the cladding temperature generally exceeds 600°C. Under these circumstances specific material properties are required for the interaction of the cladding with steam and for the mechanical strength.

4.6.1 High-Temperature Corrosion

The cladding-steam reaction model is often based on parabolic kinetic correlations for both the oxygen mass gain and or the ZrO_2 layer thickness growth. The actual reaction rate constant is defined as a function of the temperature through an Arrhenius relation

$$K_m = A_m \exp\left(-\frac{Q_m}{T}\right) \quad (67)$$

where K_m is the oxygen mass gain rate in $\text{mg}/\text{cm}^2/\text{s}^{1/2}$, A_m is the pre-exponential factor, Q_m is the activation energy divided by the perfect gas constant, and T is the cladding temperature in Kelvin.

The kinetics of high-temperature oxidation of Zircaloy were described by Baker and Just (1962) by the following equation: (B-J)

$$w = 2029t^{0.5} \exp\left(\frac{-11,450}{T}\right) \quad (68)$$

where w is the weight of metal zirconium reacted per unit surface in mg/cm^2 , T is the temperature in Kelvin, and t is the time (at the constant temperature T) in seconds. Although a more precise correlation was derived subsequently, the Baker-Just correlation is quoted here because it is the reference correlation for expressing the cladding zero ductility criterion for LOCA accidents, as will be discussed in ► 6.4. An improved correlation (C-P) was developed by Cathcart et al. (1977):

$$w = 601.8t^{0.5} \exp\left(\frac{-10050}{T}\right) \quad (69)$$

The two above correlations are compared in ► Fig. 11, in terms of temperature and time needed to achieve the same level of oxidation (17% of metal) for a two-side oxidation of a PWR 17×17 cladding. As one can notice, the B-J correlation is somewhat more conservative in that in the high-temperature range the given oxidation level (17%) is predicted for somewhat lower temperature and/or lower time as compared with the C-P correlation. The difference is of approximately 50°C in the temperature interval 1100–1200°C, whereas it is practically negligible in the 800–1000°C range.

Typical correlations for the Zr1%Nb-specific alloy were published by Solyany et al. (1983).

$$K_m = 920 \exp\left(-\frac{10,410}{T}\right) \quad (70)$$

and Gyori et al. (2003, 2008)

$$K_m = 658 \exp\left(-\frac{10,200}{T}\right) \quad (71)$$

■ Figure 11

Comparison of the Baker–Just (B–J) (Baker and Just 1962) and the Cathcart–Powel (C–P) (Cathcart et al. 1977) correlations in terms of time–temperature dependence to achieve 17% oxidation (PWR 17×17 cladding)

At higher temperatures, only data published by Urbanic et al. (1978) are available for Zircaloy. At 1,853 K, which is close to the monoclinic to cubic transformation of the oxide, a discontinuity has been observed in the oxidation rate.

The equations above indicate that the oxidation rate (at constant temperature) is not constant with time but decreases as it progresses, since the metal reacted progresses with the square root of time. In other words, as the oxidation progresses, there appears to be a protective effect induced by the oxide layer created in the oxidation process itself. Hence the question arises as to whether this protective effect is also effective for cladding that has been subjected to corrosion during base irradiation, as it would be the case for high burnup cladding. The experimental evidence on this particular point is scarce and to some extent contradictory. Tests done in Japan (JAEA) indicated that corroded cladding does not offer any protection against the effects of high-temperature oxidation (Nagase and Fuketa 2004). Experiments done at Argonne National Laboratory (ANL) on the other hand, indicated a “partial” protective effect of the preexisting corrosion oxide layer (Billone et al. 2008).

The reason for this difference might be due to the different experimental technique used at JAEA and ANL, or to the different morphology of the preexisting oxide layer, but is at present unclear. From the application viewpoint it thus appears that since the experimental evidence is inconclusive, LOCA analyses should not take credit of any beneficial effect of the preexisting corrosion layer on the high temperature oxidation process, unless clear and consistent evidence of a protective effect is produced. In other words, high burnup fuel with a certain corrosion layer should be treated as fresh (non-corroded cladding) for the purpose of computing the oxidation kinetics in a LOCA, unless further experimental evidence is brought forward on this particular point.

An additional observation regards the way the high-temperature oxidation correlations Eq. (68) and Eq. (69) are to be used in practice. In fact, these correlations were derived from constant temperature tests, whereas in practical LOCA applications the temperature varies with time. The procedure suggested here is to calculate the oxidation at the end of a time-step t by

means of the following algorithm (e.g., for the C-P correlation):

$$w = 0.6018(t_e + \delta t_n)^{0.5} \exp(-10050/T_n) \quad (72)$$

where T_n is the average temperature in the time interval δt_n and t_e is an equivalent time, defined as the time that would be needed to achieve the oxidation present at start of the time-step δt_n , if the temperature up to that moment had always been constant and equal to T_n .

4.6.2 High-Temperature Deformation

In fuel performance codes, usually a one-dimensional mechanical model is applied for the radial cladding deformation. For dealing with large high-temperature deformation (i.e., ballooning), typically during a LOCA-type accident, generally a strain rate correlation in the form of a Norton power equation is applied:

$$\frac{d\varepsilon_{eff}}{dt} = A \cdot \sigma_{eff}^n \cdot \exp\left(-\frac{Q}{R \cdot T}\right) \quad (73)$$

where ε_{eff} is the effective strain, σ_{eff} represents the effective stress, R is the universal gas constant, T is the temperature, A is the strength coefficient, Q is the activation energy for the plastic deformation, and n is the stress exponent.

The parameters of the Norton equation (A , Q , and n) are generally defined separately for the α and the β phases of the different cladding alloys. Indeed, at high temperatures, such as during a LOCA, the cladding may undergo a phase transition from the HCP α phase to the FCC β phase. In order to define the effective strain rate of the cladding in the metallurgical phase transition range there are two different approaches proposed in the literature. According to the first approach, the Norton parameters A , n , and Q are interpolated in the transition range using the fractions of the α and β phases as weighting factors. The second approach is based on micro-mechanical considerations for composite materials assuming a statistically homogeneous distribution of α -phase inclusions embedded in the β -phase matrix, that is, each representative volume element has the same α to β volume fraction corresponding to the macroscopic average value. According to the basic relation of self-consistency the overall average strain, and consequently the macroscopic strain rate of the two-phase cladding is expressed as the weighted average of the strain rates of each phases:

$$\dot{\varepsilon} = (1 - \phi) \cdot \dot{\varepsilon}_\alpha + \phi \cdot \dot{\varepsilon}_\beta \quad (74)$$

where ϕ is the fraction of β phase.

5 Basic Phenomena for In-Reactor Performance

The main objective of this section is the review of the main equations and boundary conditions required to describe the thermal-mechanical behavior of the nuclear fuel rods. The accurate description of the fuel rod's behavior, however, involves various disciplines ranging from chemistry, nuclear and solid state physics, metallurgy, ceramics and applied mechanics. The strong interrelationship between these disciplines calls for the development of computer codes describing the general fuel behavior. Fuel designers and safety authorities rely heavily on this type of

codes since they require minimal costs in comparison with the costs of an experiment or an unexpected fuel rod failure.

5.1 Neutronic Aspects of Nuclear Fuel Rods

5.1.1 Nuclide Evolution in Nuclear Fuel

A part of each fuel performance code deals with the calculation of the local concentrations of various actinide isotopes such as U, Pu, and some fission products (e.g., Xe, Kr, Cs, I, He) as a function of the radial position across a fuel pellet. These local quantities are required for the determination of the local power density, the local burnup, and the source term of fission products.

The radial variation of the power is due to the self-shielding effect, which is both energetic and spatial in nature. The energy self-shielding results from the resonances in the various cross sections of the nuclides present in the fuel. The spatial self-shielding effect results from the heterogeneity of a reactor. Indeed, neutron absorption at the outside of a fuel pellet will effectively shield the inside of the pellet, resulting in a neutron flux depression in the center of a fuel rod. This is strongly influenced by the neutron spectrum of the reactor.

With the present fuel discharge burnup levels in excess of 50 GWd/t, the large radial gradient of the concentrations of fissile isotopes in the fuel leads to a strong radial dependence of the power generation and the related discharge burnup. The power density provides the source term for the temperature calculation, affecting most mechanisms in the fuel. In view of the primary importance of the relative radial power profile for the thermal and mechanical analysis of nuclear fuel rods, priority is given to relative rather than absolute concentrations in fuel performance codes. Such a code receives the absolute linear heat rate (kW/m) on input at each time-step. In order to compute that radial power profile as a function of time various models are available. The main equations will be presented in the next section.

5.1.2 The Basic Equations

Rather than solving the Boltzmann transport equation for neutrons as in the WIMS (Newton and Hutton 2002) or HELIOS (Stammler 1996) lattice reactor physics codes, which are in use by the nuclear industry in fuel management calculations for nuclear power reactors, fuel performance codes must make use of simpler models for the sake of calculation time. Most of them were derived from the RADAR model (Palmer 1983), which is based on thermal neutron diffusion theory and was validated with WIMS calculations. The original TUBRNP (Lassmann et al. 1994) model for power and burnup calculations included in the TRANSURANUS fuel performance code (Lassmann 1992), and later also in other codes such as FRAPCON3 (Berna 1997), extended the RADAR model by including higher Pu isotopes, and modifying the radial shape function that accounts for resonance absorption by ^{238}U . TUBRNP was originally validated for UO_2 fuel in LWRs with experimental data from fuel with burnup values between 35 and 64 MWd/kgHM. Later the RAPID model (Lee et al. 2000) was developed for the COSMOS code (Lee et al. 2007), and PLUTON (Lemehov et al. 2001) was developed for the FEMAXI code (Suzuki 2000), while a specific burnup model for the RTOP code (Kurchatov et al. 2002) was developed for fuel rods in

Russian-type WWER reactors. RAPID was validated purely on the basis of profiles calculated by HELIOS up to 150 MWd/kgHM, while the others were validated against experimental data up to 83 MWd/kgHM.

The main equations of the simple diffusion-based models consist of a differential equation for the ^{235}U concentration, a differential equation for the ^{239}Pu concentration, and the solution of diffusion theory for the thermal flux, by assuming proportionality of the local power density $q'''(r)$ to the neutron flux $\phi(r)$, the concentrations of the relevant isotopes $N_k(r)$, and to the corresponding one-group fission cross sections $\sigma_{f,k}$ that are averaged over the neutron spectrum:

$$q'''(r) \propto \sigma_{f,k} N_k(r) \phi(r) \quad (75)$$

In order to determine ϕ thermal flux diffusion theory can be applied:

$$\nabla \phi - \kappa^2 \phi(r) = 0 \quad (76)$$

where the inverse diffusion length

$$\kappa = \sqrt{\frac{\sum_{a,tot}}{D}} \quad (77)$$

is derived from the macroscopic absorption and scattering cross sections:

$$\sum_{a,tot} \approx \sum_k \sigma_{a,k} N_k \quad (78)$$

$$D = \frac{1}{3 \sum_s} = \frac{1}{3 \sigma_s N_{tot}} \quad (79)$$

The resulting solutions of the differential equation are based on the modified Bessel functions (of the first and second type):

$$\phi(r) \propto I_0(\kappa r) \quad (80)$$

for the solid cylinder and

$$\phi(r) \propto I_0(\kappa r) + \frac{I_1(\kappa R)}{K_1(\kappa R)} K_0(\kappa r) \quad (81)$$

for the hollow cylinder, where R denotes the fuel at the outer radius.

The main disadvantage of models derived from RADAR is that they take only the formation of ^{239}Pu into account, that is, the formation of ^{240}Pu and higher Pu isotopes is neglected. In order to eliminate some of the high burnup limitations of the RADAR model, more elaborated models have been developed. The modeling of the radial power profiles is hence split into the approximation of the neutron flux through thermal diffusion theory and the computation of the local concentrations of the relevant actinide isotopes that are either fissile or fertile. As an example the equations implemented in the most recent TUBRNP model (Schubert et al. 2008) are given in ► Table 5. In this table $N_k(r)$ denotes the local concentration of the isotope N_k , σ_a and σ_b are the one-group effective cross sections for total neutron absorption and neutron capture, respectively, and “A” is a conversion constant

$$A = 0.8815 \frac{\rho_{fuel}}{\alpha \sum_k \sigma_{f,k} N_k} \quad (82)$$

where ρ_{fuel} represents the fuel density, and the time-step or the increment of the neutron fluence Φdt has been replaced by a burnup increment

$$dbu = \frac{q'''dt}{\rho_{fuel}} = \frac{\alpha}{\rho_{fuel}} \sum_k \sigma_{f,k} N_k \phi dt \quad (83)$$

This evaluation assumes a quasi-immediate β -decay of ^{237}U and ^{238}Np analogous to modeling the generation of ^{239}Pu by neutron capture of ^{238}U and quasi-immediate β -decay of ^{239}U and ^{239}Np . The concept of one group, spectrum-averaged cross sections is also used in codes such as ORIGEN (Croff et al. 1978) and KORIGEN (Fischer and Wiese 1983).

Resonance absorptions of epithermal neutrons in ^{238}U and ^{240}Pu give rise to enhanced plutonium production near the surface of the pellet. This plutonium is distributed radially according to an empirical function for the sake of simplicity:

$$f(r) = 1 + 3 \exp\left(-9.7\sqrt{R-r}\right) \quad (84)$$

in the original RADAR model (Palmer et al. 1983), and

$$f(r) = 1 + p_1 \exp\left(-p_2(R-r)^{p_3}\right) \quad (85)$$

in the TUBRNP model (Lassmann et al. 1994), where R is the fuel outer radius. While the value of p_1 differs between LWRs ($p_1 = 3.45$) and the Halden HWR ($p_1 = 2.21$), the values of $p_2 = 3.0$ and $p_3 = 0.45$ hold for both reactor types. Owing to the asymptotic behavior of expression for $f(r)$ at the minimum and maximum pellet radii, the main parameter p_1 can be interpreted as an estimate of the ratio of integrals for resonance and thermal neutrons:

$$p_1 = \frac{\int_{res} \sigma_c(E) \phi(E) dE}{\int_{th} \sigma_c(E) \phi(E) dE} \quad (86)$$

where $\sigma_c(E)$ is the differential neutron capture cross section and $\phi(E)$ denotes the neutron flux per energy. As a result, the parameter $p_1(^{240}\text{Pu})$ can be estimated on the basis of $p_1(^{238}\text{U})$ as follows:

$$\frac{p_1(^{240}\text{Pu})}{p_1(^{238}\text{U})} = \frac{RI(^{240}\text{Pu})}{\sigma_{c,th} (^{240}\text{Pu})} \frac{\sigma_{c,th} (^{238}\text{U})}{RI(^{238}\text{U})} \quad (87)$$

where RI are the resonance integrals and $\sigma_{c,th}$ are the thermal neutron capture cross-sections of the given isotopes. The applied values (► Table 4) originate from (Chadwick et al. 2006; Nichols et al. 2005) and a recent reanalysis of the thermal neutron capture cross section in ^{238}U (Trkov et al. 2005).

The system of ordinary differential equations is solved incrementally. For each average burnup increment a new radial power density profile is calculated from which the radial burnup profile is updated. Finally, the local concentrations of Kr, Xe, Cs, and Nd, are obtained by multiplying the local burnup increment by the appropriate fission yields.

Under irradiation conditions of UO_2 and $(\text{U,Pu})\text{O}_2$ fuels, three main sources for production of He have to be considered: (n,α) reactions on oxygen, ternary fission of actinides, and α -decay of actinides. The last nuclide in the above-mentioned set of ordinary differential equations is ^4He and accounts for α -decay from ^{242}Cm , ^{238}Pu , and ^{244}Cm .

■ Table 4

Resonance integrals (RI) and thermal neutron capture cross sections ($\sigma_{c,th}$) of the isotopes ^{238}U and ^{240}Pu

	^{238}U	^{240}Pu
RI	277 b	2.68 b
$\sigma_{c,th}$	8450 b	290 b

■ Table 5

Basic equations for modeling the radial burnup profile in nuclear fuels

$\frac{d^{235}\text{U}(r)}{dbu}$	$= -\sigma_{\alpha,235\text{U}}^{235}\text{U}(r)A$
$\frac{d^{236}\text{U}(r)}{dbu}$	$= -\sigma_{\alpha,236\text{U}}^{236}\text{U}(r)A + \sigma_{c,235\text{U}}^{235}\text{U}(r)A$
$\frac{d^{237}\text{Np}(r)}{dbu}$	$= -\sigma_{\alpha,237\text{Np}}^{237}\text{Np}(r)A + \sigma_{c,236\text{U}}^{236}\text{U}(r)A + \sigma_{(n,2n),238\text{U}}^{238}\text{U}(r)A$
$\frac{d^{238}\text{U}(r)}{dbu}$	$= -\sigma_{\alpha,238\text{U}}^{238}\text{U}(r)f_{238\text{U}}(r)A - \sigma_{(n,2n),238\text{U}}^{238}\text{U}(r)A$
$\frac{d^{238}\text{Pu}(r)}{dbu}$	$= -\sigma_{\alpha,238\text{Pu}}^{238}\text{Pu}(r)A + \sigma_{c,237\text{Np}}^{237}\text{Np}(r)A + \frac{\lambda_{242\text{Cm}}^{242}\text{Cm}(r)A}{\Phi} - \frac{\lambda_{238\text{Pu}}^{238}\text{Pu}(r)A}{\Phi}$
$\frac{d^{239}\text{Pu}(r)}{dbu}$	$= -\sigma_{\alpha,239\text{Pu}}^{239}\text{Pu}(r)A + \sigma_{c,238\text{Pu}}^{238}\text{Pu}(r)A + \sigma_{c,238\text{U}}^{238}\text{U}(r)f_{238\text{U}}(r)A$
$\frac{d^{240}\text{Pu}(r)}{dbu}$	$= -\sigma_{\alpha,240\text{Pu}}^{240}\text{Pu}(r)f_{240\text{Pu}}(r)A + \sigma_{c,239\text{Pu}}^{239}\text{Pu}(r)A + \frac{\lambda_{244\text{Cm}}^{244}\text{Cm}(r)A}{\Phi}$
$\frac{d^{241}\text{Pu}(r)}{dbu}$	$= -\sigma_{\alpha,241\text{Pu}}^{241}\text{Pu}(r)A + \sigma_{c,240\text{Pu}}^{240}\text{Pu}(r)A - \frac{\lambda_{241\text{Pu}}^{241}\text{Pu}(r)A}{\Phi}$
$\frac{d^{242}\text{Pu}(r)}{dbu}$	$= -\sigma_{\alpha,242\text{Pu}}^{242}\text{Pu}(r)A + \sigma_{c,241\text{Pu}}^{241}\text{Pu}(r)A$
$\frac{d^{243}\text{Pu}(r)}{dbu}$	$= -\sigma_{\alpha,243\text{Pu}}^{243}\text{Pu}(r)A + \sigma_{c,242\text{Pu}}^{242}\text{Pu}(r)A - \frac{\lambda_{243\text{Pu}}^{243}\text{Pu}(r)A}{\Phi}$
$\frac{d^{241}\text{Am}(r)}{dbu}$	$= -\sigma_{\alpha,241\text{Am}}^{241}\text{Am}(r)A + \sigma_{c,241\text{Pu}}^{241}\text{Pu}(r)A$
$\frac{d^{242}\text{Am}(r)}{dbu}$	$= -\sigma_{\alpha,242\text{Am}}^{242}\text{Am}(r)A + \sigma_{c,241\text{Am}}^{241}\text{Am}(r)A - \frac{\lambda_{242\text{Am}}^{242}\text{Am}(r)A}{\Phi}$
$\frac{d^{243}\text{Am}(r)}{dbu}$	$= -\sigma_{\alpha,243\text{Am}}^{243}\text{Am}(r)A + \sigma_{c,242\text{Am}}^{242}\text{Am}(r)A + \sigma_{c,242\text{Pu}}^{242}\text{Pu}(r)A$
$\frac{d^{244}\text{Am}(r)}{dbu}$	$= -\sigma_{\alpha,244\text{Am}}^{244}\text{Am}(r)A + \sigma_{c,243\text{Am}}^{243}\text{Am}(r)A - \frac{\lambda_{244\text{Am}}^{244}\text{Am}(r)A}{\Phi}$
$\frac{d^{242}\text{Cm}(r)}{dbu}$	$= -\sigma_{\alpha,242\text{Cm}}^{242}\text{Cm}(r)A + \sigma_{c,241\text{Am}}^{241}\text{Am}(r)A - \frac{\lambda_{242\text{Cm}}^{242}\text{Cm}(r)A}{\Phi}$
$\frac{d^{243}\text{Cm}(r)}{dbu}$	$= -\sigma_{\alpha,243\text{Cm}}^{243}\text{Cm}(r)A + \sigma_{c,242\text{Cm}}^{242}\text{Cm}(r)A$
$\frac{d^{244}\text{Cm}(r)}{dbu}$	$= -\sigma_{\alpha,244\text{Cm}}^{244}\text{Cm}(r)A + \sigma_{c,243\text{Cm}}^{243}\text{Cm}(r)A + \sigma_{c,243\text{Am}}^{243}\text{Am}(r)A - \frac{\lambda_{244\text{Cm}}^{244}\text{Cm}(r)A}{\Phi}$
$\frac{d^{245}\text{Cm}(r)}{dbu}$	$= -\sigma_{\alpha,245\text{Cm}}^{245}\text{Cm}(r)A + \sigma_{c,244\text{Cm}}^{244}\text{Cm}(r)A$
$\frac{d^{246}\text{Cm}(r)}{dbu}$	$= +\sigma_{c,245\text{Cm}}^{245}\text{Cm}(r)A$
$\frac{d^4\text{He}(r)}{dbu}$	$= \frac{\lambda_{242\text{Cm}}^{242}\text{Cm}(r)A}{\Phi} + \frac{\lambda_{244\text{Cm}}^{244}\text{Cm}(r)A}{\Phi} + \frac{\lambda_{238\text{Pu}}^{238}\text{Pu}(r)A}{\Phi}$

For a typical UO_2 fuel, the contributions of the decay of ^{244}Cm , ^{242}Cm , and ^{238}Pu amount to at least 90% of the total ^4He generation at end of irradiation. The discrepancy becomes more significant with higher power density and during a storage period. The total amount of generated ^4He in UO_2 fuel is, however, rather low – the maximum corresponding to approximately 20% of the ^4He present in MOX fuel. On the other hand, in MOX fuel the contribution of the nuclides ^{244}Cm , ^{242}Cm , and ^{238}Pu is almost equal to the total generation of ^4He by α -decay.

5.1.3 Burnable Absorbers

The need to improve reactor performance through longer cycle lengths or improved fuel utilization has been apparent since the beginning of commercial nuclear power generation. The fuel initial enrichment has been increased to almost 5%, with the consequence that the additional amount of fissile material in the core at beginning of life has had to be compensated for by the introduction of additional absorber material in the core (IAEA 1995). This additional absorber can be introduced in the form of control rods, soluble absorber (boric acid) in the coolant, integral burnable absorbers (IBA), or burnable poison rod assemblies (BPRA). IBAs are nonremovable, neutron-absorbing materials used as components of a fuel assembly. BPRAs are assemblies that contain only rods with neutron-absorbing materials that can be inserted in PWR assembly guide tubes. There are two disadvantages to the use of BPRA's. First their use results in a separate radioactive waste item, which is normally placed in a discharged fuel assembly and must be separately disposed of. Secondly, the BPRA creates a water displacement reactivity penalty at the end of cycle by virtue of it taking up the space in the guide tubes where the water moderator would otherwise be, thus hardening the spectrum. Both type of burnable absorbers can be used to control core reactivity and local power peaking and optimize fuel utilization. In general, both are designed to function during the first cycle of irradiation of a fresh, unirradiated fuel assembly.

For all BWRs integral burnable absorbers in the fuel are chosen. For PWRs the use of soluble absorber in the coolant was for many years the only burnable poison control required. However, the increase of initial fuel enrichment and the development of the ultra low leakage in-in-out fuel management scheme could not be indefinitely compensated for by increasing the boric acid concentration and therefore integral burnable absorbers and discrete burnable poison rod absorbers are also utilized in PWR designs nowadays. Burnable poisons allow fresh fuel to be placed in the center of a reactor core in an "ultra low leakage" design. The burnable poisons quench the high reactivity of the new fuel and help maintain a constant power and flux within the reactor core that is below the maximum safety standard allowed for the reactor. This low-leakage core also converts more fertile material to fissile material than a core with the fresh fuel loaded on the outside of the reactor allowing a greater proportion of the fuel to be burned by the end of life (EOL). The low-leakage design also helps eliminate damage to the pressure vessel due to neutrons escaping from the core. In addition, the highly efficient shuffle schemes made possible by the BPRA and integral burnable poisons have reduced ore requirements by >3% and separative work requirements by >4%.

Two concepts of integral burnable absorbers are treated in general, namely Gadolinia (Gd_2O_3) and Zirconium diboride (ZrB_2). Gadolinium addition to the fuel is considered to have several significant effects on fuel performance, such as degrading the thermal conductivity

of the fuel (see ► Sect. 3.2.2), reducing the melting point and producing a distorted, rapidly changing radial power profile. Only the last aspect will be treated here.

Natural gadolinium consists of seven isotopes with mass numbers 152, 154, 155, 156, 157, 158, and 160. The natural percent abundances are 0.002, 0.021, 0.148, 0.206, 0.157, 0.248, and 0.218 respectively. This burnable absorber works by neutron capture of two isotopes, ^{155}Gd and ^{157}Gd , with extremely high absorption cross sections. The isotopes produced by this reaction, ^{156}Gd and ^{158}Gd have a small absorption cross section and need not to be further considered.

The methodology to describe the neutron absorption of ^{155}Gd and ^{157}Gd is the same as in previous burnup equations, that is,

$$\frac{d\text{Gd}_{155}}{dbu} = -\sigma_{a,155}\text{Gd}_{155}A \quad (88)$$

$$\frac{d\text{Gd}_{157}}{dbu} = -\sigma_{a,157}\text{Gd}_{157}A \quad (89)$$

The difficulty of this simplified treatment is the definition of the effective absorption cross section σ_a . The absorption cross section is extremely high for neutron energies below 1 eV. The consequence is (1) a local shift of the neutron spectrum of the thermal flux (hardening) and (2) a significant spatial self-shielding of the fuel. One can try to fit the effective absorption cross section so that the local change of the neutron spectrum is approximately taken into account. Nevertheless, the self-shielding is solved with the diffusion approximation, which is not valid in strong absorbing media. It leads to an underestimation of the power and the central temperature by the fuel performance code at beginning-of-life (BOL). In order to cope with Gd more accurately, it is therefore recommended to apply tables with relative power profiles obtained by means of transport codes such as WIMS or HELIOS.

The second burnable absorber was developed by Westinghouse under the name IFBA (Integral Fuel Burnable Absorber). This fuel consists of a thin layer ZrB_2 ($\sim 200\ \mu\text{m}$) deposited by sputtering on the surface of the UO_2 pellets. The resulting loading is $1.7\ \text{mg}\ ^{10}\text{B}$ per cm and the layer adheres perfectly to the UO_2 substrate (IAEA 1995). This burnable absorber in the form of a thin layer works through the (n,α) reaction, for example, He is produced. As a result there is a need to reduce the pre-pressurization level of the fuel rod. Apart from this, the methodology to describe the neutron absorption of boron is the same as in the case of Gadolinia.

5.2 Heat Transfer and Thermal Characteristics

The objective of this section is to describe how the temperature distribution in a nuclear fuel rod is calculated in a fuel rod performance code. The scope is limited to a description of the important physical phenomena, along with the basic equations and the main assumptions. Detailed numerical aspects as well as mathematical derivations are provided in (Bailly et al. 1999; Lassmann and Van Uffelen 2004; Olander 1976).

The temperature distribution in a fuel rod is of primary importance for several reasons. First of all, the commercial oxide fuels have poor thermal conductivity, resulting in high temperatures even at modest power ratings. Secondly, fuel performance codes are used for safety cases where one has to show that no fuel melting will occur, or that the rod internal pressure will remain below a certain limit. Finally, many other properties and mechanisms are exponentially dependent on temperature.

The most important quantity is of course the local power density q''' , that is, the produced energy per unit volume and time. It is usually assumed that q''' depends only on the radius and the time. The linear rating q' is then simply given by

$$q' = \int_{r_{f,i}}^{r_{cl,o}} q''' 2\pi r dr = \int_{r_{f,i}}^{r_{f,o}} \bar{q}_f''' f(r) 2\pi r dr + \int_{r_{cl,i}}^{r_{cl,o}} \bar{q}_{cl}''' 2\pi r dr \quad (90)$$

where $r_{f,i}/r_{cl,i}$ is the inner fuel/cladding radius, $r_{f,o}/r_{cl,o}$ is the outer fuel/cladding radius, $\bar{q}_f'''$ and $\bar{q}_{cl}'''$ are the average power density in the fuel and cladding, respectively, and $f(r)$ is a radial distribution (form) function obtained from the neutronic calculations (cf. ► 5.1). Generally, the linear rating is a prescribed quantity and is a function of the axial coordinate z and the time t . For some phenomena (e.g., cladding creep), the neutron flux is also needed. It can be prescribed as well but may also be calculated from the local power density.

5.2.1 Axial Heat Transport in the Coolant

In general, three regimes must be covered in a LWR:

1. The subcooled regime, where only surface boiling occurs. This regime is typical for PWR's under normal operating conditions.
2. The saturated, two-phase regime. This regime is typical for BWR's under normal operating conditions.
3. The saturated or overheated regime. This regime may be reached in all off-normal situations. A typical example is a LOCA.

The fuel rod performance codes use one-dimensional (axial) fluid dynamic equations that can only cope with the first two regimes. For simulating the third type of regime, the whole reactor coolant system needs to be analyzed by means of thermo-hydraulic system codes such as RELAP or ATHLET.

The temperature calculation in the coolant serves two purposes. First of all, the axial coolant temperature in the basic (fictional) channel provides the (Dirichlet) boundary condition for the radial temperature distribution in the fuel rod. It results from the combined solution of the mass, momentum, and energy balance equations. The simplified equation used in fuel performance codes reads

$$c\rho \frac{\partial T}{\partial t} + c\rho w \frac{\partial T}{\partial Z} = q_{cl,c}'' \frac{2\pi r_{cl,o}}{A} + q_c''' \quad (91)$$

where c represents the heat capacity, ρ the density, w the velocity, T the temperature, $q_{cl,c}''$ the heat flux from the cladding to the coolant, A the channel cross-sectional area, $r_{cl,o}$ the cladding outer radius, and q_c''' the power density in the coolant. In general, the heat flux from cladding to coolant should be computed by means of a thermo-hydraulic code. Mathematically, the boundary condition is of the convective type

$$q_{cl,c}'' = -\lambda \frac{\partial T(r,t)}{\partial r} \Big|_{r=r_{cl,o}} = \alpha \{ T(r=r_{cl,o}) - T_c \} \quad (92)$$

where α is the heat transfer coefficient between cladding and coolant and $T_c = T_c(z, t)$ is the (bulk) coolant temperature. Only for a steady-state condition

$$c\rho w \frac{dT}{dZ} = \frac{q'}{A} + q''' \quad (93)$$

the heat flux from the cladding to the coolant is known and is given by

$$q''_{cl,c} = \frac{q'}{2\pi r_{cl,o}} \quad (94)$$

Under normal operational conditions, the mass flow rate, the coolant inlet temperature, and pressure are prescribed. In an off-normal or accidental situation the normal operational condition is the initial condition, but the boundary conditions must be provided by the thermo-hydraulic system codes.

The second objective of the heat flow calculation in the coolant is the derivation of the radial temperature drop between the coolant and the cladding $T_{cl} - T_c$, resulting from convection:

$$q'' = \alpha_{\text{film}}(T_{cl} - T_c) = \frac{q'_c}{2\pi r_{cl,o}} \quad (95)$$

The heat transfer coefficient in the film depends on the type of convection (forced or natural) and the type of coolant (gas, liquid, liquid metal). In the subcooled regime of a PWR, the Dittus-Boelter correlation is largely applied, whereas in the saturated regime of a BWR the Jens-Lottes correlation is applied.

5.2.2 Heat Transport through the Cladding

The heat transport through the cladding occurs through conduction:

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \lambda_c \frac{\partial T}{\partial r} \right) + q'''_{cl} = 0 \quad (96)$$

where λ_c is the cladding conductivity (~ 20 W/mK for Zircaloy), and q'''_{cl} the heat generation in the cladding (gamma-heating, as well as the exothermic clad oxidation process). In order to account for the presence of an outside oxide layer with a thermal conductivity on the order of 2 W/mK for ZrO_2 (thickness $< 100 \mu\text{m}$), the total equivalent cladding conductivity can be obtained by applying the formula for serial thermal resistances. In a similar manner, the appearance of crud on the outer cladding surface is sometimes accounted for through an additional heat transfer coefficient. The word crud stems from Chalk River unidentified deposits, that is, the filtered reactor coolant that contained metal fragments. Crud builds up in the reactor coolant over time and becomes extremely radioactive. It gathers in elbows of the piping system and when coolant pumps are started or shifted, the rapid change in turbulent water flow in the pipes causes a crud burst. Some of the crud is deposited on the cladding, but because of its varying composition and attachment, it is difficult to predict accurately its contribution to the heat transfer in the fuel rod.

5.2.3 Heat Transport from the Cladding to the Fuel Pellet

The temperature difference in the pellet-cladding gap, ΔT_{gap} , is calculated as follows (Lassmann and Hohlefeld 1987):

$$\Delta T_{gap} = \frac{q''}{h_{gap}} \quad (97)$$

where q'' is the heat flux in W per unit area and h_{gap} is the heat transfer coefficient between fuel and cladding (gap conductance). Heat transfer by convection can be neglected. In general, the heat transfer coefficient h_{gap} depends on

- Gap width or contact pressure between fuel and cladding;
- Gas pressure and composition;
- Surface characteristics of cladding and fuel.

In fact, there are three parallel conduction routes:

$$h_{gap} = h_{rad} + h_{con} + h_{gas} \quad (98)$$

The contribution of the radiative component is given by

$$h_{rad} = \left(\frac{C_s}{\frac{1}{\varepsilon_f} + \frac{1}{\varepsilon_{cl}} - 1} \right) \frac{T_f^4 - T_{cl}^4}{T_f - T_{cl}} \quad (99)$$

where C_s is the Stefan–Boltzmann constant, ε the emissivity, and T the temperature. The radiative component is less than 1% during normal operating conditions, because of the limited surface temperatures.

The component h_{con} reproduces the improvement in heat transfer due to contact pressure

$$h_{con} = \alpha \bar{\lambda} \delta \left(\frac{P}{\delta^2 H} \right)^\beta \quad (100)$$

where $\bar{\lambda}$ and δ are the mean values of the thermal conductivity and the arithmetic mean roughness, respectively, P is the contact pressure, H is the Meyer hardness of the softer material, α and β are model parameters.

The heat transfer by conduction in the gas is often based on the model of Ross and Stoute (1962):

$$h_{gas} = \frac{\lambda_{gas}}{\delta + s + g_f + g_{cl}} \quad (101)$$

where the thermal conductivity of a multicomponent gas is only composition dependent and calculated by means of

$$\lambda_{gas} = \sum_{j=1}^n \left[\frac{\lambda_j}{\left(1 + \sum_{k=1, j \neq k}^n w_{jk} \frac{c_k}{c_j} \right)} \right] \quad (102)$$

with c and w being molar concentrations and weighting factors respectively. The gas extrapolation lengths g_f and g_{cl} (or temperature jump distance) account for the imperfect heat transport across the solid–gas interface, which is material and gas-pressure dependent. Detailed formulations are discussed in Lassmann and Hohlefeld (1987).

5.2.4 Effects of Irradiation on Gap Conductance

As a result of the release of fission gases from the fuel pellets, the thermal conductivity of the plenum gas will change. As shown in ► Fig. 12 the released fission gases (Kr, Xe) have a much lower thermal conductivity than the helium-filling gas. According to Eq. 102 the thermal conductivity of the He–Kr–Xe mixtures can be written as

$$\lambda_{gas} = \frac{\lambda_1}{1 + A_{12}(x_2/x_1) + A_{13}(x_3/x_1)} + \frac{\lambda_2}{1 + A_{21}(x_1/x_2) + A_{23}(x_3/x_2)} + \frac{\lambda_3}{1 + A_{32}(x_1/x_3) + A_{31}(x_2/x_3)} \quad (103)$$

where subscripts $j, k = 1, 2$, and 3 denote He, Kr, and Xe, respectively, and A_{jk} are empirical coefficients. Since the fission gas release in LWR fuel during normal operation is around 1% of the inventory, the fraction of (Xe + Kr) steadily increases as a function of burnup, which according to Eq. 103 leads to a lower thermal conductance of the gap. For example, the thermal conductivity decreases by about a factor of 2 when the concentration of Xe and Kr released to the gap and plenum increases to about 27%. At the same time the pressure in the free volume of the pin increases. This latter effect on the thermal conductivity is, however, small and can be neglected on the basis of the known data for helium (Tseiderberg et al. 1971).

► Figure 13 shows the thermal conductivity of a (He + Kr + Xe) gas mixture typical for a PWR fuel rod as a function of burnup calculated using Eq. 103. The A_{jk} coefficients are taken from (Yamnikov and Malanchenko 1977):

$$\begin{aligned} A_{12} &= 2.7 & A_{13} &= 3.6 \\ A_{21} &= 1.7 & A_{23} &= 0.6 \\ A_{31} &= 0.5 & A_{32} &= 3.5 \end{aligned}$$

It is important to note that, despite very detailed formulations for the gap conductance, there is an unavoidable uncertainty in the gap sizes due to input uncertainties, but also because of uncertainties in the mechanical computation (e.g., cracking and fuel swelling, as discussed below).

5.2.5 Heat Transport in the Fuel Pellet

The heat produced by the slowing down of the fission fragments in the fuel pellets is removed through conduction in the pellets:

$$\rho c \frac{\partial T}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left(\lambda r \frac{\partial T}{\partial r} \right) + q''' \quad (104)$$

where c is the specific heat at constant pressure for fuel. The boundary conditions are

$$\text{Inner boundary : } \frac{\partial T(r = r_i, t)}{\partial r} = 0 \text{ (radial symmetry)}$$

$$\text{Outer boundary : } \Delta T_{gap} = \frac{q''}{h_{gap}} \text{ (pellet surface temperature is known)}$$

■ Figure 12

The thermal conductivity of helium and the fission gases krypton and xenon at atmospheric pressure as a function of temperature (Hanley 1973; Häussinger et al. 1991)

■ Figure 13

The thermal conductivity of the (He + Kr + Xe) gas mixture in the free volume of a PWR fuel rod at $T = 800$ K (black curve) as a function of burnup as calculated from Eq. (103) and the corresponding fraction of krypton and xenon (red curve). The discontinuities in the curves correspond to changes in the power between reactor cycles

The temperature distribution in the pellets is therefore affected by two terms: the heat source and the fuel thermal conductivity. At beginning-of-life (BOL), the heat production in LWRs is subject to a slight (typically in the range of 10%) depression, that is, $q'''_{BOL} \approx l_0(r)$, where $l_0(r)$ is the modified Bessel function. During the irradiation of the fuel, epithermal neutrons are captured preferentially near to the surface of the fuel by ^{238}U . This leads to an enrichment of ^{239}Pu at the outer periphery of the fuel. At end of life (EOL), $q'''_{f,0} \propto (2 - 2)q'''_{f,i}$, that is, the power density distribution is a steep function of the radius (see Fig. 14). This effect needs

■ Figure 14

Radial form factor of the power density q''' at beginning and end of life for “typical” LWR conditions according to the TUBRNP model (Lassmann et al. 1998). The radial distribution of the power density depends on enrichment, rod diameter, neutron spectrum, and other parameters

therefore to be considered and a specific model for the radial power density such as TUBRNP is a prerequisite for any temperature analysis at high burnup.

The thermal conductivity of the fuel is specified in ➤ Sect. 3.2.

5.3 Mechanical Behavior

The first barrier against release of radioactive fission products to the environment is the cladding of the nuclear fuel rod. The stress and associated deformation assessment of the cladding are therefore essential in fuel performance calculations. Furthermore, the deformation of both the pellets and the cladding affects the gap width, which in turn affects the conductance of the gap, hence the temperature distribution in the pellets. The thermal and mechanical analyses are therefore equally important and closely coupled. In principle, both problems should therefore be solved simultaneously. In practice, however, all fuel performance codes solve them separately but provide coupling through an iterative scheme. This important numerical aspect will not be dealt with here. The interested reader is referred to a general discussion on this issue in Lassmann (1980, 1992) and Lassmann and Hohlefeld (1987).

The following sections summarize how stress and strains are calculated in both the ceramic pellets and the metallic cladding, while underlining the main assumptions and limitations.

5.3.1 Main Assumptions and Equations

The main assumptions generally made in fuel performance codes are as follows:

- The system is axisymmetric, that is, variables do not vary tangentially.

- Although the fuel and cladding move axially (not necessarily at the same rate), planes perpendicular to the z -axis remain plane during deformation (plain strain condition), that is, the rod remains cylindrical.
- Dynamic forces are in general not treated, and the time dependence inherent in the analysis (creep) is handled incrementally.
- Elastic constants are isotropic and constant within a cylindrical ring.
- The total strain can be written as the sum of elastic and nonelastic components.

The first two assumptions reduce the problem to one dimension. The third assumption indicates that the stresses are related through a local equilibrium condition for the radial force in the following form:

$$\frac{d\sigma_r}{dR} = \frac{\sigma_t - \sigma_r}{R} \quad (105)$$

where σ_r and σ_t represent the normal radial and tangential stress, respectively, and R corresponds to the radius of the deformed geometry.

Since the fuel stack and cladding are treated as a continuous, uncracked medium, no discontinuities are allowed in their displacements. This is translated by the compatibility relations for the strains

$$\varepsilon_r = \frac{dU}{dR} \quad (106)$$

$$\varepsilon_t = \frac{u}{R} \quad (107)$$

$$\varepsilon_a = \text{constant} = C_3 \quad (108)$$

where u represents the radial deformation and ε_i are the normal strains.

Finally, the last equation relates the stresses to the strains. Based on the fifth assumption, the constitutive relations read

$$\underline{\varepsilon}^{\text{total}} = \underline{\varepsilon}^{\text{elastic}} + \sum \underline{\varepsilon}^{\text{nonelastic}} \quad (109)$$

where

$$\underline{\varepsilon} = \begin{Bmatrix} \varepsilon_r \\ \varepsilon_t \\ \varepsilon_a \end{Bmatrix} \quad (110)$$

5.3.2 Calculation of Strains

Elastic Strain

The elastic strains for an isotropic material are reversible and given by

$$\varepsilon_r^{\text{elastic}} = \frac{1}{E} [\sigma_r - \nu(\sigma_t + \sigma_a)] \quad (111)$$

$$\varepsilon_t^{\text{elastic}} = \frac{1}{E} [\sigma_t - \nu(\sigma_r + \sigma_a)] \quad (112)$$

$$\varepsilon_a^{\text{elastic}} = \frac{1}{E} [\sigma_a - \nu(\sigma_r + \sigma_t)] \quad (113)$$

Figure 15

Elongation of UO_2 fuel and Zircaloy cladding due to thermal expansion (-), as a function of the temperature

Nonelastic Strain

The nonelastic strains consist of various contributions. First of all, there is the thermal strain resulting from temperature differences, which is assumed to be isotropic and reversible

$$\varepsilon_i^t = \alpha(T - T_0) \quad i \in r, t, a \quad (114)$$

The thermal expansion coefficients depend on the material and the temperature itself, as shown in ► Fig. 15. The larger thermal expansion of UO_2 with respect to that of zircaloy explains why thermal expansion is one of the largest contributions to the gap closure in a nuclear fuel rod at beginning-of-life.

The second contribution to the nonelastic strain in the fuel pellets comes from swelling, and is also assumed to be isotropic. The fuel swelling in turn has four contributions:

$$\varepsilon_{fuel}^s = \frac{1}{3} \left[\left(\frac{\Delta V}{V} \right)_{solid FP} + \left(\frac{\Delta V}{V} \right)_{gaseous FP} - \left(\frac{\Delta V}{V} \right)_{densification} - \left(\frac{\Delta V}{V} \right)_{hotpressing} \right] \quad (115)$$

where the first term is attributed to the inexorable swelling of solid fission products:

$$\left(\frac{\Delta V}{V} \right)_{solid FP} = bu \left(\sum_{solid FP} Y_i \frac{v_i}{v_u} - 1 \right) \quad (116)$$

which is linearly dependent on burnup, the fission product yield (Y_i), and on the partial volume of the species (v_i). In general, the solid fission product swelling is on the order of 1% per 10 GWd/t. The second term comes from gaseous fission product swelling:

$$\left(\frac{\Delta V}{V} \right)_{gaseous FP} = \frac{4\pi}{3} \int_0^{R_{max}} R^3 N(R) dR \quad (117)$$

and requires a model to predict the gaseous fission product behavior, more precisely the gas bubble formation due to the low solubility of rare gases in UO_2 (cf. below). During the initial

■ Figure 16

Change of the fuel pellet stack length (mm) at beginning-of-life as a function of the burnup (MWd/kgUO₂), showing the combined effect of densification and solid fission product swelling

stages of the irradiation ($bu < 10$ MWd/kgHM), the density increases as some fabrication porosity disappears as a result of the impact of fission fragments on the (small) pores. In general, the shrinkage process depends on the temperature, burnup, fission rate as well as a combination of the initial density, the pore size distribution, and the grain size. The ideal situation is thus to have a fundamental model for densification, such as those proposed by Assmann and Stehle (1978) and Suk et al. (1992). However, values for the parameters involved are not always well known. Therefore, many code developers have implemented empirical correlations for the fraction of the original porosity, which has annealed out as a function of the local burnup, the temperature and the grain size, for example (Jackson et al. 1990):

$$\frac{\Delta P}{P_0} = \alpha [1 - \beta \exp(-a_1 bu) - (1 - \beta) \exp(-a_2 bu)] \quad (118)$$

where $\alpha = (T/^\circ\text{C} - 83)/(288D_{gr})$, $\beta = 5.12 \exp(-5,100/(T/K))$, $a_2 = 0.0016 \text{ tUO}_2/\text{MWd}$, $a_1 = 100a_2$. The densification, together with the solid fission product swelling is illustrated in

► Fig. 16.

Under the influence of high temperatures, stress levels, and defect production rates during irradiation, a fraction of the fabrication porosity will disappear. This fourth contribution to fuel swelling is referred to as hot pressing and is similar to creep (see below). Therefore, either vacancy diffusion:

$$\frac{dP}{dt} = -K\alpha \left(\frac{\Omega D_{vol}}{kT} \right) \frac{P}{R_{gr}^2} \sigma \quad (119)$$

or plastic flow (i.e., dislocation climb or other model of creep)

$$\frac{dP}{dt} = -\frac{9}{4}\alpha\sigma P \quad (120)$$

are considered.

The isotropic swelling strain in the cladding is due solely to void formation, hence it requires a model for the evolution of voids in the metal.

The third contribution to the nonelastic strain in the fuel is visco-plastic in nature. It consists of instantaneous plastic deformation when the yield stress is exceeded and of time-dependent creep. For the fuel and cladding a simple isotropic plastic flow model can be applied. Nevertheless, as creep is the main contributor to stress relaxation after cracking (see below) in the oxide pellets, it is often only considered in the cladding.

In a multiaxial state of stress a method of relating the onset of plastic deformation to the results of a uniaxial test is required. Furthermore, when plastic deformation takes place one needs to determine (1) how much plastic deformation has occurred and (2) how that deformation is distributed among the individual components of strain. For the first requirement a so-called yield-function is needed. This may be one-dimensional such as the Mises criterion (Cunningham et al. 2001; Suzuki 2000):

$$\sigma_{eff} = \frac{1}{\sqrt{2}} \left[(\sigma_r - \sigma_t)^2 + (\sigma_r - \sigma_a)^2 + (\sigma_t - \sigma_a)^2 \right]^{1/2} \quad (121)$$

so that yielding only occurs when the effective or equivalent stress (σ_{eff}) exceeds the yield stress determined from a uniaxial tensile test. Others have introduced the anisotropic factors according to Hill's methodology (Lassmann and Van Uffelen 2004). Finally, a multidimensional yield surface (Garcia et al. 2002; Oguma 1983) has also been proposed. In order to account for work hardening, one generally assumes that the yield stress changes with the total permanent deformation. The plastic strain is therefore computed incrementally.

In order to answer the second question, each increment of effective plastic strain is related to the individual plastic strain components by a flow rule

$$\Delta \varepsilon_i = \Delta \varepsilon_{eff} \frac{\partial \sigma_{eff}}{\partial \sigma_i} \quad i \in r, t, a \quad (122)$$

When using the above-mentioned definition of the equivalent stress, one obtains the Prandtl-Reuss flow rule

$$\Delta \varepsilon_i^p = \frac{3\Delta \varepsilon_{eff}^p}{2\sigma_i} S_i \quad (123)$$

indicating that the plastic strain increment is proportional to the deviatoric stress $S_i = \sigma_i - \sigma_h$ where $\sigma_h = (\sigma_r + \sigma_t + \sigma_a)/3$.

For the time-dependent creep one needs strain rate equations, although the total creep strain is also computed incrementally by multiplying the strain rate with the time-step length. For primary creep, typically an empirical expression is applied:

$$\dot{\varepsilon}_{eff} = K \sigma_{eff}^n t^m \quad (124)$$

where K, n, m are constants.

For the secondary or steady-state creep, there are three parallel processes. The vacancy diffusion or Nabarro–Herring creep and the dislocation climb are dominating at high temperature and high stresses, respectively:

$$\dot{\epsilon}_{eff}^c = \frac{Bq''' \sigma_{eff}}{R_{gr}^2} \exp\left(-\frac{E}{kT}\right) \quad \text{vacancy diffusion} \quad (125)$$

$$\dot{\epsilon}_{eff}^c = B' q''' \sigma_{eff}^{4.5} \exp\left(-\frac{E}{kT}\right) \quad \text{dislocation climb} \quad (126)$$

The third process is irradiation-induced creep, dominating at low temperatures and assumed to be proportional to the effective stress and the local fission rate density or q''' .

The fourth and last nonelastic strain component stems from the pellet cracking. Pellet cracking already occurs at startup due to the differential thermal expansion since the hot pellet center expands more than the cold periphery. In order to assess the linear heat generating rate at which cracking in cylindrical pellet occurs, the maximum thermal stress ($= \sigma_{t,max} = \sigma_{a,max}$ at pellet periphery) in an uncracked pellet submitted to a parabolic temperature gradient

$$\sigma_{t,max} = -\frac{\alpha E q'}{8\pi(1-\nu)\lambda} \quad (127)$$

must be compared with the (uniaxial) fracture stress, which is approximately 130 MPa. When using $E = 200$ GPa, $\nu = 0.31$, the thermal diffusivity $\alpha = 10^{-5} \text{ K}^{-1}$, and an average thermal conductivity of $\lambda = 3 \text{ W/mK}$ radial cracks are predicted to be initiated in the pellet periphery at a linear heat rate q' of the order of 5 kW/m. The number of cracks (N_{cr}) is dependent on the linear heat rate. Oguma (1983) proposed a linear model for the number of radial cracks that is illustrated in Fig. 17. In addition to radial, also axial and (especially under ramping conditions) circumferential cracks are formed (Fig. 18).

The consequences of cracking are very important in fuel performance modeling. Owing to the larger thermal expansion of the fuel fragments in comparison with that of a monolithic

■ Figure 19

Radial temperature distribution in a BWR-rod (IFA-505) at beginning-of-life (BOL) calculated by the TRANSURANUS code. Comparison between the analysis of a Xe-filled rod with (full line) and without (dashed line) taking relocation into account

■ Figure 20

Fraction of gap closure due to pellet fragment relocation (δ_g), derived from the relocation model in the `frapcon3` code

cylinder, and due to vibration-induced motion they move outward. This is called pellet “relocation” and has a strong impact on the thermal behavior as shown in ► Fig. 19. It reduces the pellet-cladding gap size, thereby reducing the temperature levels in the fuel at beginning-of-life. This constitutes the largest contribution to the gap closure (approximately 30–50%, depending on q') but is also the one that is subject to the largest uncertainty, because of the stochastic nature of the cracking process. This also raises questions about the usefulness of applying three-dimensional stress calculations.

The contribution from relocation is generally accounted for in the tangential strain component as a (linear) function of the linear heat rate: $\varepsilon_t = u/r$, where $u = s\delta_g$, s being the initial radial gap size and δ_g the fraction of the gap size closing as a result of relocation. An example based on the relocation model in the `FRAPCON3` code (Berna et al. 1997) is illustrated in ► Fig. 20 (Lassmann et al. 2005).

When the pellets relocate to such an extent that they come into contact with the cladding, which creeps down under influence of the pressure difference between the coolant pressure and the fill gas pressure, then relocation may be (partly) reversed.

The effect of relocation on the mechanical behavior is also of primary importance since it reduces the overall stress in the pellets and may even change the sign of the stress in central part of the pellet from compression (in a cylinder) to traction (in fragments) (Van Uffelen et al. 2004). To account for the cracks exactly would require the exact location and size of every crack and to solve a three-dimensional stress-strain problem in each block. Instead, one simply modifies either the material constants (Lassmann et al. 2005; Suzuki 2000) or modifies the constitutive equations. An example of the former approach is that of Jankus and Weeks (1972), where a reduction of the elastic constants is proposed:

$$E' = \left(\frac{2}{3}\right)^{N_{cr}} E \quad (128)$$

$$v' = \left(\frac{1}{2}\right)^{N_{cr}} v \quad (129)$$

which means that an equivalent continuous and homogeneous solid body with directionally dependent (anisotropic) properties is considered. As the pellet-clad gap closes during irradiation the contact pressure can press the fragments inward, thereby reducing the relocated radius to a minimum value. Some codes also account for the restoration of the elastic constants as the relocation is reversed (partially) (Suzuki 2000).

In order to modify the constitutive equations, a plane stress condition has been proposed (Garcia et al. 2002), that is the tangential stress is set equal to the fill gas pressure once the radial crack appears. Both types of approaches, however, do not account for crack healing.

5.3.3 Boundary Conditions

In order to solve the main equations summarized in the previous sections, boundary conditions are required.

Radial Boundary Conditions

In general, continuity of the radial stress and displacement at each radial zone is imposed and the radial stress at the outer cladding surface is determined by the coolant pressure: $\sigma_r(r_{cl,o}) = -p_{cool}$.

The boundary condition in the rod depends on the configuration. When pellet-cladding mechanical interaction is not established, the radial stress at the pellet periphery is determined by the fill gas pressure in the fuel rod (p_{gas}): $\sigma_r(r_{f,o}) = -p_{gas}$. For the boundary condition in the pellet center, two possibilities exist. In hollow pellets, the radial stress at the pellet center is equal to fill gas pressure as well: $\sigma_r(r_{f,i}) = -p_{gas}$, whereas in the event of full cylindrical pellets the radial and tangential stresses are equal in the pellet center.

When the fuel and cladding are in contact, a fuel pellet interfacial pressure exists (p_{fc}) and determines the boundary condition at the pellet surface: $\sigma_r(r_{f,o}) = \sigma_r(r_{cl,i}) = -p_{fc}$. The other radial boundary conditions remain unchanged.

Axial Boundary Conditions

The plane strain assumption entails that the axial strain is constant in the plane perpendicular to the axial axis. The axial strain is therefore determined by an axial force balance equation including the fill gas pressure, the plenum spring pressure, the fuel column weight, and the friction forces. The latter depend on the fuel-cladding interaction and can only be taken into account iteratively. Indeed, when a section i is analyzed it is not known whether friction forces between fuel and cladding originating from a section above/below i need to be considered in the axial balance of forces. This is schematically shown in  Fig. 21. In the case of a radial contact between fuel and cladding both bodies may stick to each other, but some sliding may be possible in specific conditions (sticking or static vs. sliding friction). Part of the fuel rod may be “trapped,” which means that rather high axial forces may act on cladding and fuel.

One advantage of two-dimensional and three-dimensional finite element models is that such effects are automatically included in the analysis through the use of specific gap elements.

■ Figure 21

Four possible modes of an interaction between fuel and cladding

5.4 Fission Gas Behavior

On average, each fission event produces 0.3 Xe and Kr atoms. These inert fission gas atoms are basically insoluble, causing two important life-limiting phenomena in the fuel rod: either they remain in the pellets and contribute to the swelling, or they are released from the pellets and increase the rod internal gas pressure while reducing the thermal heat transfer in the gap (see ▶ Sect. 5.2.4). The fuel swelling may lead to pellet-cladding mechanical interaction and even cladding failure under certain conditions. Likewise, the fission gas release may lead to higher fuel rod temperatures, which in turn could lead to higher fission gas release until the rod fails due to clad ballooning and clad burst.

Because of its implications for fuel performance, the basic mechanisms involved in the fission gas release and swelling in LWR fuel will be summarized first, before outlining how these phenomena are implemented in a code. The interested reader will find more details in Van Uffelen (2002).

5.4.1 Basic Mechanisms

Recoil, Knockout and Sputtering

In general, a fission event entails – among others – two fission fragments that transfer their kinetic energy to the fuel lattice. A fission fragment, close enough to a free surface ($<6\text{--}7\text{ }\mu\text{m}$), can escape from the fuel due to its high kinetic energy (60–100 MeV). This is called recoil release. When fission fragments make elastic collisions with the nuclei of lattice atoms, a collision cascade appears. The interaction of a fission fragment, a collision cascade, or a fission spike with a stationary gas atom near the surface can also cause the latter to be ejected if it happens within a distance close enough to the surface. This process is called release by knockout. Finally, the energy loss of a fission fragment traveling through the oxide crystal lattice causes a high local heat pulse. When this happens close to the fuel surface, a heated zone will evaporate or sputter, thereby releasing any fission product contained in the evaporated zone.

Recoil, knockout, and sputtering can only be observed at temperatures below 1000°C , when thermally activated processes (cf. below) do not dominate. They are almost temperature independent and therefore called athermal mechanisms. It is generally of little importance in reactor at intermediate burnup levels. The fraction of athermal release is roughly under 1% for rod burnup below 45 MWd/kgU, and accelerates to roughly 3% when the burnup reaches about 60 MWd/kgU.

Lattice Diffusion of Single Gas Atoms

The first and basic step in fission gas release is single gas atom diffusion in the lattice. Possible mechanisms by which the inert gas atoms migrate through the fuel have been studied by Grimes and Catlow (1991) by considering low-energy migration pathways between solution sites as well as the stability of gas atoms at a variety of solution sites within a defective UO_{2+x} lattice ($x = |O/M - 2|$, the deviation of the stoichiometry). They postulate a cation vacancy-controlled migration pathway for Xe atoms. Indeed, according to his calculations, Xe is trapped at a uranium vacancy in UO_{2+x} , at a tri-vacancy cluster in UO_{2-x} and at a di- or tri-vacancy in UO_2 . Since the local environment of the migrating Xe atoms is supposed to become the charged tetra-vacancy for all stoichiometries, the mechanism for diffusion only considers the association of a cation vacancy to the trap sites. (Uranium vacancies as the slower moving species are rate-controlling for most diffusion-related processes in UO_2).

The lattice diffusion coefficient is influenced by the temperature, deviations from stoichiometry and additives (e.g., Cr, Nb), phase changes and therefore also indirectly by the burnup. Also the fission fragments are assumed to contribute to the diffusion process, which is referred to as irradiation-enhanced diffusion. This is due to the interaction of the fission fragments and the associated irradiation damage cascades with the fission gas atoms in the

lattice, resulting in a displacement of the gas atoms. Indeed, there is a constant process of slowing down fission products in the fuel causing fission spikes or tracks to be formed. The spikes have a length in the order of 7 microns, wherein about 15,000 U-Frenkel pairs are produced instantaneously (Matzke 1980). Only 5,000 pairs remain after direct annihilation. The width of the permanently disturbed zone is approximately 7 nm. Significant temperature increases along the axis occur causing larger hydrostatic pressure gradients leading, for example, to a separation of vacancies from interstitials and hence a largely temperature-independent, athermal radiation-enhanced diffusion, as well as resolution of inert gas atoms from bubbles or even complete destruction of bubbles nuclei or small bubbles. Each atom is affected by a fission spike at a rate of once in a few hours to once in a day, depending on the reactor type.

A consistent set of radiation-enhanced diffusion coefficients (D^*) is available for metal self-diffusion (Matzke 1980). In as far as these data may be due to a mixing of atoms in the course of fission spikes, the D^* values will apply for gases as well. However, no firm conclusions emerge as to the mechanism. Atomic scale simulations could shed light on the details of this mechanism. Despite the lack of details, D^* has been shown to be directly proportional to the fission rate density (F'): $D^* = AF'$, where $A = 1.2 \cdot 10^{-29} \text{ cm}^5$ for oxide fuels.

Since $D^{Xe} > D^U$, the thermally activated temperature regime for fission gas diffusion extends to lower temperatures than D_U . A radiation-enhanced diffusion coefficient will therefore only be operative in the cold outer rim of the fuel. However, at temperatures between 1,000 and 1,400°C, there appears to be some influence of the irradiation as well, leading to a lower activation enthalpy for the single gas atom diffusion coefficient.

Irradiation-induced migration dominates the diffusion process at temperatures below 1,000°C and is temperature independent. For temperatures between 1,000 and 1,400°C, vacancies necessary for the gas atom diffusion are assumed to be created both thermally and by the damage cascades related to fission fragments. Above 1,400°C, a purely thermally activated diffusion coefficient is applied, that is, thermally created vacancies for diffusion are predominant. These three temperature regimes are reflected in the three components of the single gas atom diffusion coefficient (m^2/s) often applied in the fuel performance codes (Turnbull et al. 1982):

$$D = D_1 + D_2 + D_3 \quad (130)$$

where

$$D_1 = 7.6 \times 10^{-6} \exp\left(-\frac{35,000}{T}\right) \quad (131)$$

$$D_2 = 5.6 \times 10^{-25} \sqrt{\dot{F}} \exp\left(-\frac{13,800}{T}\right) \quad (132)$$

$$D_3 = 8 \times 10^{-40} \dot{F} \quad (133)$$

where $\dot{F}$ is the fission rate density and T is the absolute temperature.

Unperturbed (intrinsic) diffusion of single inert gas atoms (Xe, Kr) can be observed at low damage and gas concentration (10^{-5} at-%). At higher gas and damage concentrations other effects should be taken into account.

Trapping

In nuclear fuels, either natural (e.g., impurities, dislocation lines, and closed pores) or radiation produced imperfections in the solid (e.g., vacancy clusters in fission tracks, fission gas bubbles, and solid fission product precipitates) depress the amount of fission products available for diffusion by temporarily or permanently trapping the migrating atoms. Experiments show that for burnups characteristic of power reactors, gas atom trapping due to (intragranular) fission gas bubbles in the grains is predominant. The trapping rate depends on the size of the intragranular bubbles, hence on temperature, fission rate, and burnup. A second important effect of trapping occurs at grain boundaries. It deals with the delay for the onset of thermal fission gas release, via the bubble interconnection mechanism (cf. below).

Irradiation-Induced Resolution

A fraction of the gas atoms trapped in bubbles can be re-dissolved in the surrounding matrix through the interaction of a fission fragment with the bubble. Although gamma-rays, neutrons, and fission fragments are all capable of causing resolution of fission gases from bubbles, only fission fragments can account for the high efficiency of the process as observed experimentally. Fission fragments not only have a higher initial kinetic energy (50–100 MeV) than fast neutrons (2 MeV), but also they are charged and consequently have a higher cross section for transferring energy either to lattice or gas atoms.

Two different types of mechanisms are proposed to explain the experimental observations (Olander 1976; Turnbull 1980). On one hand, microscopic models consider the resolution of one gas atom at a time when interacting with a fission fragment or an energetic atom from the collision cascade. These models do not predict complete bubble destruction – as suggested from experimental observations (Blank and Matzke 1973; Turnbull 1980) – since only about 10% of the initial fission fragment energy is lost in direct collisions with lattice ions while the rest is first dissipated in the electronic structure of the material through which it passes by means of Rutherford collisions. Macroscopic models on the other hand consider the complete bubble destruction, but there is still discussion about the detailed mechanisms. Despite this, the balance of opinion favors a mechanism based on fission fragment energy loss via electron excitation leading to a cylindrical heat distribution around the fission track along with a compressive thermoelastic pulse (Blank and Matzke 1973; Olander 1976; Ronchi and Elton 1986; Turnbull 1980). Regardless of the type of model adopted, one can express the rate at which gas atoms are redissolved from a bubble by means of the macroscopic model of Turnbull (1980), which lead to Eq. (140). Nevertheless, for (larger) grain boundary bubbles resolution is supposed to be less effective.

Grain Boundary Diffusion

Grain boundary diffusion is the most commonly observed route for solute migration in polycrystalline materials. It is generally accepted that diffusion in crystalline solids proceeds more rapidly along grain boundaries than through the lattice. This is due to the atomic jump frequency in these planar defects, which is about a million times greater than the jump frequency of regular lattice atoms in stoichiometric materials at 0.6 times the absolute melting temperature. Nevertheless, there is a switch from release assisted by grain boundary diffusion in trace-irradiated UO_2 to trapping and eventual interlinkage of the intergranular bubbles (cf. below). This switch occurs early in life, so that grain boundary diffusion is only considered to

contribute to the precipitation of fission gas atoms in grain boundary bubbles, rather than to the long-range transport along grain boundaries to the free surface of the pellets (Olander and Uffelen 2001).

Grain Boundary Sweeping or Grain Growth

In LWR fuel under normal operating conditions, only normal grain growth is observed, that is, large grains grow at the expense of smaller ones. It affects fission gas release in two ways. First of all, grain boundary sweeping provides another mechanism for the collection of gas at these internal surfaces from which release can occur. The collection results from the low solubility of the fission gas, hence the sweeping grain boundary does not redeposit any gas in the newly formed crystal behind it. The moving grain boundary acts as a fission gas filter. Secondly, the average diffusion distance for the fission products created in the grain increases. Unlike the first consequence this tends to reduce the release rate. Grain boundary sweeping occurs at temperatures above roughly 1,600°C.

Bubble Migration

The migration of fission gas bubbles provides an alternative to the sequence “bubble formation-resolution-gas atom diffusion” in order to describe fission product release from nuclear fuels. Migration of bubbles in the oxide fuels has two other important consequences, namely the columnar grain growth with the concomitant central void formation (observed in fast breeder reactor fuel), and the coalescence of the bubbles, which gives rise to fuel swelling. Under normal operating conditions, however, fission gas bubbles remain small (typically below 20 nm) due to resolution, and show a small mobility at least up to 1,800°C (Matzke 1980). This is partly explained by the pinning by dislocations and other crystal defects.

Bubble Interconnection

Fission gas bubbles appear along grain boundaries after a certain burnup, depending on the temperature history. When bubbles interconnect, they form a so-called tunnel network through which the gas can be released. The bubble interconnection is a reversible process, for the tunnel network can close again under the influence of the surface tension when the outgoing flux of gas atoms outweighs their supply.

The bubble interconnection has two important consequences. First of all, it determines the onset of release as the release remains small (due to athermal release) before grain boundary bubbles interconnect with open grain edge tunnels. This incubation period is reflected in the Halden threshold for fission gas release, which is shown in  Fig. 22. The ensuing release corresponds to a seepage process. Secondly, when grain face bubbles interconnect and form snake-like tunnels, there will be a sudden release of the gas accumulated in these bubbles, referred to as burst release. This can also be interpreted as a sudden interconnection or opening of grain face bubbles due to micro-cracking along grain boundaries during abrupt power variations. Cracking entails a sudden opening of a fraction of the grain boundaries with the instantaneous venting of the corresponding fraction of the accumulated gas atoms. Interconnection of gas-filled bubbles takes place in general where diffusion-controlled precipitation occurs at the grain boundaries, that is, when both T and the burnup are high enough. The

■ Figure 22

Original Halden criterion for the onset of fission gas release and supporting data (Vitanza et al. 1978)

conditions correspond roughly to the Halden threshold (Vitanza et al. 1978; Wiesenack 1997)

$$T_c(^{\circ}\text{C}) = \frac{9,800}{\ln\left(\frac{bu}{0.005}\right)} \quad (134)$$

where T_c represents the central temperature in degree Celsius, and bu the burnup in MWd/kgUO₂.

5.4.2 Modeling the Fission Gas Behavior

There are various approaches in fission gas release and swelling modeling. They can be classified into two categories. On one hand there are purely empirical models, including those based on soft computing techniques such as neural networks. These models are inexpensive to use and provide an efficient tool for the design of fuel rods within a limited range of application. However, they are not suitable for gaining knowledge about the underlying mechanisms, nor do they enable us to extend their range of application to higher discharge burnup values as required by the industry. On the other hand, there are mechanistic models that aim at the physical description of the underlying phenomena. Despite their need for a large database, such models provide an excellent basis, both for the analysis of the mechanisms, as well as for the extension of the models beyond their range of calibration.

Fuel performance codes nowadays tend to implement more and more mechanistic models, based on very detailed but stand-alone models. They all consider fission gas release to be a two-step process. The first step deals with the gas behavior in the grains (intragranular part),

whereas the second step deals with the gas behavior along the grain boundaries (intergranular part).

Intragranular Behavior

For the behavior in the fuel grains, the following scenario is generally adopted. The gas atoms are created by fission in the fuel matrix. They then diffuse in the grains toward grain boundaries by thermal- and irradiation-enhanced diffusion. Small intragranular bubbles with a diameter of 1 to 2 nm are observed in irradiated fuel. They are created in the wake of fission spikes and then grow by diffusion (trapping). They are continuously destroyed by fission spikes (resolution). There is no bubble migration except at temperatures above roughly 1,800°C. The bubbles act as sinks for gas atoms, thereby reducing the amount of gas available for release.

This scenario leads to solving a diffusion equation in a sphere with a source term proportional to the local fission rate density ($S = Y_f \dot{F}$), which is based on the pioneering model of Booth (1957a). He proposed the equivalent sphere model. This theory considers a polycrystalline sintered body as a collection of uniform spheres with an equivalent radius in order to simplify the mathematical problem. The hypothetical sphere radius (R_B) is defined so that the effective surface-to-volume ratio of the fuel (S/V) is preserved:

$$\frac{1}{R_B} = \frac{1}{3} \left(\frac{S}{V} \right)_t \quad (135)$$

where $(S/V)_t$ accounts for the sum of the geometric surface of the pellets as well as the surface due to open porosity. As irradiation proceeds, fission gases are generated within the Booth sphere and migrate to the surface, where the concentration is taken to be zero. He proposed that the fractions of stable gas release can be approximated by

$$f_{ann}(t) \simeq 6 \sqrt{\frac{Dt}{\pi R_{gr}^2}} - 3 \frac{Dt}{R_{gr}^2} \quad (136)$$

for so-called annealing conditions (i.e., without source term, but with an initial nonzero concentration), and

$$f_{irr}(t) \simeq 4 \sqrt{\frac{Dt}{\pi R_{gr}^2}} - \frac{3}{2} \frac{Dt}{R_{gr}^2} \quad (137)$$

for irradiation conditions (nonzero source term, but no initial concentration). In a second model Booth (1957b) proposed the approximation for the release-to-birth ratio for unstable gas release under steady-state conditions to be

$$\frac{R}{B} = \frac{3}{R_{grain}} \sqrt{\frac{D}{\lambda}} \left[\coth \left(R_{grain} \sqrt{\frac{\lambda}{D}} - \frac{1}{R_{grain}} \sqrt{\frac{D}{\lambda}} \right) \right] \quad (138)$$

where λ represents the decay constant of the species under consideration. It should be underlined that the diffusion coefficient to be used is subject to an order of magnitude uncertainty. Eq. (130) in the previous section is often being used, with a multiplication or reduction factor of about 5.

Regardless of the uncertainty on the diffusion coefficient, the Booth models themselves suffer from several limitations:

1. They consider a constant temperature and fission rate density
2. They do not account for resolution and trapping at intragranular bubbles
3. They do not account for grain boundary sweeping
4. They cannot reproduce an incubation period (cf. Halden curve)
5. They do not account for resolution at grain boundary bubbles

All of these limitations have been alleviated over time. First, several numerical techniques have been proposed to cope with time-varying conditions, which have been compared in Lassmann and Benk (2000). In order to deal with trapping and resolution, Speight (1969) found that instead of solving one diffusion equation coupled with an equation for the gas balance in the traps, one could solve a single diffusion equation for the sum of the concentration in the matrix and in the traps with an effective diffusion coefficient (D_{eff}):

$$D_{eff} = D \frac{b}{b + g} \quad (139)$$

where $g = 4\pi R_{bubble} d$ corresponds to the trapping rate coefficient and b corresponds to the resolution rate coefficient. Whatever model is being considered for resolution, fission gas behavior models generally introduce a simple resolution rate coefficient that is proportional to the local fission rate density and depends on the bubble size:

$$b = 2\pi(R_{bl} + \delta)^2 \mu_{ff} \dot{F} \quad (140)$$

where it is assumed that a bubble can be destroyed if its center lies within a distance δ from the fission fragment track of length $\mu_{ff} = 7\text{--}10 \mu m$. The condition for applying D_{eff} , is that the traps are saturated. Experiments show that small intragranular bubbles stabilize rapidly both in size and in diameter. Intragranular bubbles can therefore be considered saturated for irradiation times of practical interest (beyond 0.5 MWd/kgU). Nevertheless, the difference between D and D_{eff} is only important for temperatures above approximately 1,100°C. It should be underlined, however, that during a power ramp the application of D_{eff} provides an overestimation of the trapping effect (Lösönen 2000).

During the course of time several models have been proposed wherein the Booth sphere radius was taken to be equal to the average grain radius of the fuel, in order to be able to account for grain growth. However, it must first be pointed out that although there is no consensus about which grain growth model should be applied, the (Ainscough et al. 1974) model is often used:

$$\frac{dR_{grain}}{dt} = k \left(\frac{1}{R_{grain}} - \frac{1}{R_{max}} \right) \quad (141)$$

where k is a temperature dependent rate constant, and $R_{max} = R_{max}(bu)$ the grain size at which growth stops. This burnup dependent quantity is introduced in order to account for the retarding effect of fission products on grain growth as burnup proceeds.

Most fission gas release models only account for the increase of the average diffusion distance when normal grain growth occurs. Some other models only take into consideration the sweeping effect, assuming either that the fractional release is proportional to the grain boundary velocity, or that the gas in the total fraction of grain volume swept by the grain boundaries

■ Figure 23

Schematic representation of a lenticular grain face bubble with radius of curvature r

is released. So they all fail to properly incorporate boundary motion into the intragranular diffusion equation and artificially separate the two aspects of grain growth on fission gas release. Only some stand-alone models have been proposed so far that account for both simultaneously by solving the diffusion equation in a sphere with a moving boundary (e.g., Forsberg and Massih (2001)).

For alleviating the fourth and fifth limitations of the Booth models, an intergranular module has to be introduced.

Intergranular Behavior

Three main different concepts are being applied. First of all, an intergranular model that does not treat the kinetics at the grain boundaries directly. In a way the Booth model is a special case of this type, in that it considers gas atoms to be released as soon as they arrive at the grain boundary. The other models in this category consider gas arriving at the grain boundaries to precipitate straight away in grain boundary bubbles. An open tunnel network is assumed to be established along the grain boundaries once a so-called saturation value for the intergranular gas atom concentration ($N_{\max}$) has been collected. In order to derive this saturation value, one assumes that

1. Intergranular bubbles are lenticular, with Θ being the dihedral angle between the grain boundary and the bubble surface (cf. ► Fig. 23)
2. A mechanical equilibrium exists between the bubble gas pressure (p_{gas}), the surface tension (γ), and the hydrostatic pressure (σ_h) in the surrounding matrix: $p_{gas} = \frac{2\gamma}{\rho_{bl}} + \sigma_h$, where ρ_{bl} is the radius of curvature of the grain boundary bubble,
3. A perfect gas law can be applied as equation-of-state.

Under those assumptions, the following expression is obtained for $N_{\max}$:

$$N_{\max} = \frac{4\rho_{bl}f(\Theta)}{3kT\sin(\Theta)^2}\phi^*\left(\frac{2\gamma}{\rho_{bl}} + \sigma_H\right) \quad (142)$$

where $f(\Theta) = 1 - \frac{3}{2} \cos \Theta + \frac{1}{2} (\cos \Theta)^3$ and ϕ^* stands for the fraction of the grain face surface occupied by the bubbles at interconnection. As soon as $N_{\max}$ is achieved, any excess gas atoms arriving at the grain boundaries are deemed released. It must be pointed out that no consensus has been reached at to what value should be applied for the hydrostatic stress. Often it is neglected, or a value is being used, which is constant and uniform. Obviously this is a rough approximation.

In a second category of models, the intergranular kinetics is being considered directly. As such, an account is made of the reversible character of the tunnel establishment. The first model was proposed by White and Tucker (1983). They considered two parallel processes for release from the Booth sphere: intragranular diffusion and gaseous diffusion through tunnels along grain boundaries. To this end they solve two different diffusion equations in the equivalent Booth sphere. More recently, Koo et al. (1994) proposed two different contributions for the S/V used to compute the equivalent Booth sphere radius. One contribution was attributed to macroscopic radial cracks in the pellet periphery, while the second contribution was ascribed to a fraction of the tunnel network along grain boundaries that was in contact with the open grain corner porosity (based on percolation theory in two dimensions). Recently, several other models have been proposed wherein the gaseous diffusion through the open tunnel network is being modeled according to Darcy's or Poiseuille's law in a tube (e.g., Kogai (1997) and Van Uffelen (2002)). These models enable the effect of the hydrostatic pressure on the release kinetics to be accounted for. More recently, White (2004) went even further with the details and modeled the evolution of the bubble morphological relaxation through differential absorption/emission of vacancies, which is surface-curvature driven. Nevertheless, these models are not yet implemented as standard models in fuel performance codes.

In a third category of models, a comprehensive list of mechanisms (cf. previous section) has been implemented in the form of a set of ordinary differential equations, that is, the intra- and intergranular parts of the model are solved simultaneously (e.g., MARGARET (Noirot 2005)). These models were essentially produced to deal with fission product behavior under severe-accident conditions. Up to now, only the FASTGRASS model of Rest et al. (1992) is being applied in the VICTORIA code (Olander and Mubayi 1999).

Coupling Intra and Intergranular Behavior

In general, the intragranular and intergranular modules of a fission gas behavior model are coupled in two directions. On one hand, the intragranular module provides the source term for the intergranular module. On the other hand, the intergranular module provides the boundary condition for the diffusion equation in the spherical grains and/or the supplementary source term near the grain boundary. In fact most models make use of the Booth approximations, that is, they assume zero boundary conditions, meaning that the grain boundary is considered to be a perfect sink. Some models consider a finite segregation factor. In order to account for the resolution effect on grain boundary bubbles, three different approaches are being utilized. The first group considers a correction factor for the Booth flux, accounting for the fact that the resolution opposes the gaseous diffusion out of the grains. The second group of models applies a time-varying boundary condition that makes use of a time dependent flux balance. In the third and last group, a supplementary source term is defined in a fine layer adjacent to the grain face, either as a uniform source in a fine layer, or as a Dirac distribution at a given distance from the grain boundary. Mainly the first two approaches have been implemented in fuel performance codes.

Swelling

Theoretically speaking, the fission gas release and the fission gas swelling models should be closely related. In most codes, however, semiempirical relations are being used for the gaseous swelling as a function of the temperature and burnup (e.g., MATPRO (1981; 1990)), or as an empirical function of the released fraction, for instance (Billaux 2005):

$$\left(\frac{\Delta V}{V}\right)_{\text{gaseous FP}} = A(1 - \alpha_{FG}FGR - \alpha_{cs}CSR)bu \quad (143)$$

where A is a constant for solid swelling, FGR the local fraction fission gas release from the grain, CSR the fractional release of the volatile fission products (Cs , I) from the grain, bu the local fuel burnup, $\alpha_{FG} = 0.37$ and $\alpha_{cs} = 0.45$. The empirical nature reflects the uncertainty pertaining to both the release and swelling models (in particular during power ramps at high burnup) as can also be inferred from the large variety of models presented above.

6 Typical Phenomena and Issues in the Design and Licensing of LWR Fuels

6.1 High Burnup Structure

6.1.1 Characteristics of the High Burnup Structure

During irradiation, the strong resonance absorption of epithermal neutrons in ^{238}U leads to the production of the isotope ^{239}U , which successively decays by β -emissions to ^{239}Np and ^{239}Pu . For fuel in the form of cylindrical pellets, maximum neutron absorption takes place at the pellet surface, hence the local plutonium concentration in UO_2 exhibits a maximum at this outer surface and decreases exponentially toward the pellet center. Subsequent fissioning of this plutonium results in a near surface enhancement of burnup compared to that throughout the rest of the pellet. At a pellet average burnup ≈ 60 MWd/kg, the local burnup within $\sim 100 \mu\text{m}$ of the pellet surface is increased by a factor 2 or 3 depending on the flux spectrum of the reactor.

In the late 1950s, it was first observed that in very high burnup UO_2 fuel a restructuring process takes place (Barney and Wemble 1958; Belle 1961). It was found that UO_2 irradiated to high burnup, 10%FIMA at relatively low temperatures, did experience a change of crystalline state (Barney and Wemble 1958). From this it was inferred that the material became amorphous. In the mid-1980s the phenomenon was observed again in power reactor fuel (Barner et al. 1990; Baron 1986).

From the various observations it was found that this zone is characterized by

1. Xe depletion (0.25 w%) from the matrix of newly formed small grains, as measured by electron-probe microanalysis EPMA,
2. Coarsened fission gas pores of micrometric size, leading to a swelling contribution up to 15%,
3. Subdivision of the initial grains from typically $10 \mu\text{m}$ to $0.15\text{--}0.30 \mu\text{m}$.

At first it was thought that the restructuring and enhanced porosity were a direct result of the production of plutonium in the rim region of the pellet. However, EPMA studies on high burnup LWR fuel by Walker et al. (1992) showed that the restructuring extended much further from the

■ Figure 24

Scanning electron micrographs of a nuclear reactor fuel of rod average burnup of 97.8 MWd/kgHM at several radial positions (Manzel and Walker 2002). ©Elsevier, 2002, reprinted with permission

pellet surface than the extent of the plutonium concentration. From these studies it was clear that the restructuring was a result of the local high burnup and not the generation of plutonium. This conclusion was supported further by Kameyama et al. (1994) who investigated the threshold for rim structure formation as a function of burnup in fuels of different initial enrichment in the high burnup effects program (HBEP) (Cunningham et al. 1992; Mogensen et al. 1999). They found that the threshold, which occurred at a local burnup of 70–80 MWd/kgU, was independent of the enrichment, which varied in their study from 1.38 to 8.25 wt% ^{235}U . The contribution of plutonium to the local burnup becomes greater in the lower enriched pellets at high burnup. They concluded that the plutonium/uranium burnup ratios did not change the threshold burnup for rim structure formation. In addition, the different enrichments ensured that the fuels operated at different power densities during irradiation. Thus the invariance of the threshold with enrichment also implied that it was insensitive to power or fission rate.

Further support for the onset of the rim structure depending only on local burnup and not on the U/Pu fission ratio, hence on plutonium concentration and heat rate, comes from the high burnup rim project (HBRP) (Kinoshita et al. 2000; Sonoda et al. 1999, 2002). In this project UO_2 disks fabricated with a ^{235}U enrichment of 26 wt% were irradiated in the Halden reactor, and discharged with a range of burnup levels up to 100 MWd/kg. Despite the extreme uranium enrichment and short time irradiation of 2–2.5 years, the onset of the rim structure occurred at burnup levels very similar to those found in lower enriched LWR fuel as discussed above by Walker et al. and Kameyama et al. Also, in the highest burnup disks, this restructuring

■ Figure 25

Comparison between measured local xenon concentrations measured by EPMA and SIMS as a function of the pellet radius (Walker et al. 2009). ©Elsevier, 2009, reprinted with permission

occurred throughout the whole volume of the disk. As a consequence, the “rim” structure has been renamed as the “high burnup structure,” HBS, because such microstructure modification can occur anywhere within the pellet at temperatures below 1000°C and depends solely on the local burnup. This is also supported by observations of HBS surrounding Pu-rich regions in some types of MOX fuels whose burnup is in excess of the surrounding matrix.

6.1.2 Importance of the High Burnup Structure

The concomitant measurement of an increase of the fractional fission gas release in LWR fuel once the rod average burnup exceeded 45 MWd/kgHM, and the Xe depletion observed by means of EPMA was first considered as an indication that there was a new release mechanism from the HBS. This was thought to be associated with the percolation through the large porosity that was collecting all the depleted Xe from the surrounding grains. In addition to such direct contribution from the HBS to the fractional release, the porosity formed in the pellet periphery was also assumed to constitute a thermal barrier. The resulting temperature increase would enhance the thermal release from the pellet interior, thereby providing an indirect contribution from the HBS to the observed increase in fission gas release. The thermal effect of the HBS was further supported by the observed thermal conductivity degradation with burnup.

The formation of the high burnup structure, however, seems to have a very positive effect on the thermal conductivity in the outer region of the fuel. The thermal conductivity in this region of the fuel is much higher than would be the case if the high burnup structure was not present. The increase in thermal conductivity caused by the formation of the high burnup structure is a consequence of the removal of fission product atoms and radiation defects from the fuel

■ Figure 26

Thermal diffusivity of the high burnup fuel at 217°C as a function of the local burnup. At $r/r_0 = 0.81$, where the local burnup was 90 MWd/kgHM, the local thermal conductivity of the fuel rod would have been 20% higher in the absence of gas pores. Five percentage porosity is a hypothetical value equating to the porosity of the fresh fuel (Walker et al. 2006); ©Elsevier, 2004, reprinted with permission

lattice during recrystallization of the fuel grains (an integral part of the formation process of the high burnup structure). The role of the pores of the high burnup structure as sinks for fission gas expelled from the fuel lattice during recrystallization is more important than their effect as barriers to heat transfer. In the outer region of the fuel, between $r/r_0 = 0.81$ and 0.66, the porosity of the high burnup structure reduced the increase in thermal conductivity caused by recrystallization between 35 and 50% at 217°C.

Recent observations (Spino et al. 2006) also indicated that the HBS porosity is not interconnected, and that release from the HBS is too small to explain the increase of overall fission gas release measured during post-irradiation examination on commercial fuel rods. Furthermore, new experimental evidence on thermal conductivity indicated that the Xe depletion in the matrix accompanying the grain restructuring results in a restoration of the thermal conductivity, the effect of which is larger than the degradation due to the porosity buildup (● Fig. 26). Combining this with a measured decrease of the hardness (Spino et al. 2006) along with an increase of the fracture toughness (Baron et al. 2005), the overall effect of the HBS on the fuel performance under normal operating conditions even seems beneficial rather than detrimental as originally feared.

The importance of the HBS during off-normal conditions, on the other hand can be of concern. However, it was observed that the gas stored in the HBS porosity may not contribute significantly to the fuel dispersal during a sudden increase of the local temperature, (e.g., during the first instants of a reactivity-initiated accident or RIA in ● Sect. 6.5), while it is still unknown

whether it can contribute to the fuel dispersal during the cooling down when fuel micro-cracks form due to thermal stress relaxation.

6.1.3 Modeling of the High Burnup Structure

In view of its implications on the fuel rod performance, the HBS has been the subject of many studies. Despite these efforts, no consensus could yet be obtained for several issues (Van Uffelen et al. 2004). The most important differences exist about the scenario describing the nucleation and growth of the HBS. This in turn is related to discussions about the driving force for the HBS formation (radiation damage and/or fission product accumulation), about the nucleation centers for the HBS nucleation (over-pressurized bubbles, grain boundaries, fabrication pores, and dislocations or so-called recrystallization nuclei), and about the parameters affecting the HBS formation and propagation (pellet-cladding contact pressure, initial grain size).

In fuel performance codes, the effect of the HBS on the heat transfer is generally included in a correlation describing the thermal conductivity degradation (cf. ► Sect. 3.2.3) and the porosity build up in the HBS as well as in an improved gap conductance in order to account for the bonding layer between the ceramic pellets and the metallic cladding. To this end, for example, the cladding and pellet roughness is empirically reduced above a certain burnup, to account for the filling up by mainly zirconium oxide, which has a higher thermal conductivity than that of the mixture of He and Xe in the residual gap.

Thermal conductivity degradation of the fuel is sometimes considered to saturate (Sontheimer et al. 1998). Occasionally partial thermal conductivity restoration is even considered when the HBS is created. In this way account is made for the *cleaning* of the matrix from point defects and fission products, which relies on an empirical formulation of the lattice parameter variation (Baron 1998). The latter approach seems to be in line with the most recent experimental data shown in ► Fig. 26.

The effect of the long irradiation time in the mechanical analysis is mostly accounted for in the cladding properties. The process of outer cladding corrosion liberates hydrogen from the water and can lead to brittle hydride formation. When these hydrides are oriented normal to the cladding surface, the cladding strength is further reduced. Reduction of the microhardness (► Fig. 27) and Young's modulus (► Fig. 28) observed in high burnup fuel pellets is not yet included in the codes. This also holds for the bond between pellet and cladding, which improves the pellet-cladding interaction resistance since it is much softer than UO_2 .

The impact of the HBS on fission gas release is incorporated in various ways. The simplest way is based on an empirical threshold depending on the local burnup, and/or temperature and/or initial grain size. Others include the burnup as a parameter in the diffusion coefficient or the S/V value (cf. Booth sphere radius in ► Sect. 5.4.2), or in the grain boundary saturation value. Quantitative details of most models are not available in the open literature. In the START3 code the grain size reduction observed is modeled in an empirical manner as a function of temperature and burnup (Bibilashvily et al. 2000). As the average distance for intragranular diffusion thereby reduces, an increased release fraction is predicted. Nevertheless, there is evidence that direct release from the HBS is small under normal operating conditions (Spino et al. 2006). Apart from this general statement that the release is small, there is no consensus about

■ Figure 27

Experimental values for microhardness of irradiated UO_2 fuel with a burnup of 98 GWd/tHM (Spino et al. 2006); ©Elsevier, 2004, reprinted with permission

the quantitative contribution from the HBS to the overall release under normal operating conditions. This is very well reflected in the large spread of fission gas release predictions at very high burnup for the codes involved in the FUMEX-II benchmark exercise organized recently by the IAEA (► Fig. 29) (Killeen et al. 2007).

Under design basis accident conditions, the release models disregard the kinetics. Release is assumed to be instantaneous (provided that the gap is open) and comes from grain boundary cracking. The precise modeling of this relies on the modeling of the local conditions of temperature and stress, which is very difficult but is hardly discussed in publications.

■ Figure 28

Experimental Young's modulus of irradiated LWR fuels as a function of burnup (Baron et al. 2005)

■ Figure 29

Cumulative fractional fission gas release predicted for a constant linear heat rate of 15 kW/m by various fuel performance codes involved in the FUMEX-II round robin exercise of the IAEA (Killeen et al. 2007)

■ Figure 30

Porosity as a function of the local burnup for highly irradiated fuel, and the corresponding correlation adopted in the transuranus code (Lassmann 2000)

Finally, the swelling in the HBS is mostly modeled separately with a very simple linear or quadratic function of burnup (► Fig. 30). Also the width of the HBS structure is sometimes modeled empirically as a function of the burnup.

6.2 Pellet-Cladding Interaction

6.2.1 Pellet-Cladding Mechanical Interaction

The high radial temperature gradient and the concomitant differential thermal swelling in the ceramic fuel pellet leads to a so-called hourglass type deformation (► Fig. 31). Indeed, even at a low linear heat generation rate of around 5 kW/m, the internal thermal stresses in the cylindrical fresh pellet exceed the fracture stress of UO_2 (around 100 MPa), causing pellet fracture. Once the pellet has fractured, it is able to deform much more readily under the effects of the temperature field, causing the pellet ends to bow outward. The pellets also swell during irradiation (► Sect. 5.3).

In line with the pellet deformation, the cladding creeps toward the pellets during the first part of the irradiation under the action of the differential pressure, that is, the difference between the pressure of the primary water circuit (about 15 MPa in PWR) and the initial internal fill gas pressure in the rod (about 6 MPa in hot conditions). Although the cladding also undergoes thermal expansion, the expansion rate of zircaloy is less than that of UO_2 , leading to a net reduction of the original clearance between both. Due to pellet hourglassing, the onset of pellet-cladding mechanical contact occurs at the inter-pellet planes. This creates primary ridges

■ **Figure 31**
Schematic representation of pellet swelling

at the cladding exterior surface observed after ramps, sometimes referred to as the bamboo structure.

The onset of pellet-cladding mechanical interaction (PCMI) is affected by a number of design and fabrication parameters. First of all, the pellet geometry is adapted to extend the onset and to mitigate PCMI. In particular, the pellet height has been reduced with respect to its diameter while chamfers were applied for delaying PCMI and reducing the probability of fuel chipping. Secondly, the rod geometry is important. More precisely, the width of the original clearance between the pellets and the cladding should be large enough. Nevertheless, the gap size is subject to many uncertainties, the largest being the pellet fragment relocation. In addition, it is generally assumed that the pellets are located concentrically within the cladding, although this is seldom the case. Any eccentricity in the stacking arrangement, resulting from fabrication or fuel rod handling, is likely to lead to premature onset of PCMI even though its effect will diminish as gap closure occurs.

Once PCMI has started, both the pellet geometry and the material properties of the interacting components influence the maximum stresses and strains as well as their evolution. Flat-ended pellet stacks will generate larger axial expansion in comparison with dished stacks, especially in fresh fuel. This is due to the fact that in flat-ended pellets the hot central part determines the maximum length change, whereas for dished pellets there is no contact between pellets along the central axis (when the power is not too high), hence the axial expansion will be controlled by outer (cooler) regions of the pellet. In practice, the ratio of axial to tangential strain can vary between 0.2 for large dishes and 2 for undished pellets (Hoppe 1980). Nevertheless, the axial expansion from flat-ended pellets can diminish with burnup because of in-pile dishing, for instance caused by densification in the hot central parts of the pellets during PCMI.

In addition to the difficulties to reproduce two-dimensional (local) pellet deformations during PCMI by means of one-dimensional fuel performance codes as explained in ► Sect. 5.3, there are other challenges to be dealt with. Apart from pellet and cladding eccentricity, which mostly affects the onset of PCMI, there are uncertainties related to the assessment of the stress

in cracked pellets, to pinching by assembly grids, as well as to the (static and dynamic) friction coefficient between pellets and cladding. In particular, the slipping is severely restricted by the interaction layer that establishes between both components after gap closure at higher burnups.

6.2.2 Irradiation-Induced Stress Corrosion Cracking

Failures during power variations are not only attributed to stress. Stresses increase at the intersection of radial crack planes, the inter-pellet planes, and the inner surface of the cladding. The brittle nature of the failure site, however, has led to the general consensus that although stress is the primary initiator, propagation of the crack is chemically assisted, thus the process is termed stress corrosion cracking (SCC). The chemical assistance for brittle cracking in all probability arises from the environment established by fission products release into the fuel-to-clad interspace with isotopes of iodine as main candidates as the principal corroding species. There is some discussion as to whether or not the corrodent must be freshly released from the fuel or whether it is sufficient for it to have accumulated in the fuel-to-clad gap throughout the irradiation period prior to the over power transient.

The morphology of SCC surfaces in Zircaloy-4 has characteristic aspects of cracking and deformation mechanisms of hexagonal close-packed metals. The vicinities of crack initiation zones are exclusively intergranular. The intergranular cracks observed in experimental reactors can range from a few to about 20 μm . The rest of the cracking surfaces are purely transgranular, a mixture of quasi-cleavage on the basal planes of zirconium and connection of these planes by plastic deformation flutting). The quasi-cleavage is enhanced by irradiation hardening, which increases the stresses and adsorption of corrosive fission products that in turn lower the surface energy of the basal planes. This explains the limited amount of intergranular crack propagation in irradiated material.

Intergranular cracks initiate above a certain stress level, in the order of 300 MPa. Laboratory experiments on precracked tubes give transgranular crack propagation rates ranging between 0.3 and 3 $\mu\text{m/s}$ in irradiated Zircaloy-4 at 350°C (Rousselier et al. 2003). The intergranular rate is much more difficult to measure, but is in the order of 0.1 $\mu\text{m/s}$. The transition from intergranular to transgranular SCC is supposed to occur at a critical stress intensity factor in the order of 3 $\text{MPa}\sqrt{m}$ for the unirradiated material. It decreases with radiation damage.

Since its discovery in CANDU reactors and BWRs in the 1970s, four factors affect the incidence of PCI-SCC failures and were reviewed by Cox (Cox 1990), as discussed below.

Sufficient Stress

Pellet Cladding Interaction (PCI) failures are induced following substantial local power variations leading to an increase of the loading on cladding: from control-blade movements in BWRs or from load follow, frequency control, and extended reduced power operation for PWRs. However, the calculation of the stress (or stress intensity) sustained by the cladding and its time dependence is very complex and is affected by the fuel geometry and the friction coefficients, as explained above. Moreover, the stress is affected by the maximum power and the change in power. Indeed, stresses imposed on the cladding arise from a combination of the maximum power subjected to the fuel, which determines the overall expansion, and the change in power

during the ramp, which establishes the increment in strain that the cladding sees over the short period during which the power is raised. The relative importance and the actual critical levels of both factors have lead to *fuelograms*, providing limits for the two factors at different burnup levels. These fuelograms depend on the fuel design.

Sufficient Time

The overall time to failure can be subdivided into two periods; an incubation time, at the end of which incipient cracks are detectable, and the propagation time during which these cracks grow through the wall. The incubation is considered as a chemical phenomenon, and the propagation time is very difficult to measure in a reactor. It was concluded that as in laboratory tests, the majority of the time to failure was incubation time, during which no apparent damage to the cladding occurred. In order to establish incubation times and crack growth rates, several international research projects have been conducted (Sartori et al. 2007). It was observed that partial through wall cracks could be observed after ramps of about 20 s, and through wall cracks for ramps of less than one minute. However, these rapid failures could only be obtained when the test fuel was submitted to a relatively high power for at least 6 h prior to the ramp, suggesting chemical conditioning of the environment within the fuel rod. Under some conditions, the intergranular crack growth can continue at the start of SCC until the stress intensity factor for transgranular propagation (K_{ISCC}) is reached. Under such conditions an *accumulated damage parameter* could be valuable. However, since the occurrence of intergranular initiation can only be demonstrated a posteriori, and since the short times to failure attained with fast ramps are almost entirely transgranular in nature, the practical value of such an accumulated damage parameter seems limited and has been omitted in modeling (Cox 1990).

Susceptible Material

Cox (1990) reviewed many laboratory experiments that were conducted to identify the metallurgical variables (yield strength, texture, residual stresses, precipitate distribution, etc.) and compositional changes that could influence the susceptibility of the cladding for SCC. The results were quite variable as no standardized test has been adopted. Furthermore, after a critical irradiation dose, it was noticed that the differences disappeared and all materials become susceptible to cracking. The influence of irradiation on SCC susceptibility caused the redirecting of research from varying the base alloy to developing protective coatings in mitigating PCI.

Proper Chemical Environment

Based on examinations of PCI failures obtained in CANDU fuel that always show some intergranular features it was concluded that iodine-induced cracking was the cause (Cox 1990). In LWRs on the other hand, the elongated grains in the stress relieved conditions, or the very small and distorted grains size in β -quenched cladding make it difficult to distinguish transgranular from intergranular features when subsequent corrosion of the fracture surface took place. In the absence of clear evidence for intergranular features on the fracture surface, it has been impossible to reach a firm conclusion about the causative agent for PCI failures. What became

clear, however, was that the right chemical atmosphere must be present inside the cladding before the ramp.

Mitigating PCI

Understanding the important variables for PCI–SCC enables fuel designers to propose solutions. More precisely, fuel designers have adapted the fuel geometry (reducing the height to diameter ratio, introducing dishes and chamfers), imposed restrictions on the power variation, modified the fuel assembly design, and applied coatings on the inner cladding surface.

In CANDU fuel, both carbon and siloxane coatings have been tested successfully, although the former has become the standard because of the lower fabrication costs. Both carbon and siloxane are applied as coating after tubing fabrication and provide a lubricating effect. The friction coefficient of CANLUB cladding is in the range of 0.15 to 0.3 instead of 0.7 to 0.9 for standard Zircaloy (Cox 1990). The benefits of graphite coating are not only limited to the lubricating effect. Tests also revealed that it forms a barrier for establishing the proper chemical environment for SCC.

In BWRs, Cu and Zr barriers were applied in the form of thin metallic layers as an integral part of the tube fabrication process. The pure zirconium (of either crystal bar or sponge origin) (Harbottle et al. 1994; Schire et al. 1994) has been adopted as the standard barrier, because irradiation experience showed that copper offered less protection after high irradiation doses. However, pure zirconium oxidizes more rapidly in comparison with zircaloy while the terminal solubility of hydrogen is lower in the liner (Van Swam 1997). Accordingly, when a primary defect occurs in the cladding for instance due to debris fretting, water ingress will oxidize both the fuel and the liner. This occurs typically in the lower (cooler) part of the fuel rod. The hydride formation near the cladding inner diameter can lead to a *sunburst* hydride and would, due to the volume increase, set up tangential stress in the zircaloy part of the cladding, which can promote crack formation. The local hydrogen absorption can cause more severe hydriding and therefore secondary defects in the form of long axial splits and circumferential cracks. Secondary cladding defects in LWR fuel can cause large releases of uranium and fission products to the primary coolant (Karlsson et al. 2004), and seems to be correlated with PCI caused for instance by control-blade movements in BWRs. Mitigating these secondary failures has been made by means of increasing the number of rods per assembly (Garner et al. 2007) (e.g., from 6×6 to 10×10 in BWR assemblies) in order to reduce the linear heat generation rate per rod, and by alloying the liner with either Fe (Hoffmann and Dewes 2004) or Sn (Sihver et al. 1997).

A more recent component of PCI resistant fuel designs is the use of softer fuel pellets obtained by means of large grained doped UO₂ for both BWR and PWR applications. Since the early 1990s, AREVA has developed an optimized chromia-doped UO₂ fuel that exhibits significantly higher performance compared to standard UO₂ (Delafoy et al. 2007). The grains are on the order 60 μm compared to 10 μm in standard UO₂, and the creep is only controlled by dislocations movements such as sliding and climbing leading to a larger creep rate (Nonon et al. 2004). As a result of the grain size increase the fuel releases less fission gas and is less prone to PCI failures during ramp tests. Post-irradiation examinations after ramp tests revealed a larger number of radial cracks on the pellet periphery. Recent two-dimensional finite element simulations of PCI have shown that this can be attributed to the larger friction due to fuel-clad bonding in high burnup fuel and the reduced fracture stress of the doped fuel (Marchal et al. 2009). The simulations also indicate that, unlike the hoop stress, the

shear stress distribution in the cladding is smoother, thanks to the reduced fracture stress.

Modeling PCI

Modeling PCI has evolved since the first attempts aiming at the fitting of the time to failure (or failure probability), maximum power, and power increase to experimental data, although the uncertainty could reach a factor 5 (Misfeldt 1977).

The initial step is either assumed to occur at preexisting flaws (Zhou et al. 2005) according to a frequency distribution, or to occur spontaneously when a threshold such as the iodine concentration is exceeded (Miller et al. 1981). More recently, Park et al. (2008) postulated that pits would generate preferentially around grain boundaries and coalesce to form a micro-crack, referred to as grain boundary pitting coalescence. The micro-crack is assumed to develop into an incipient crack, initiating and propagating along the grain boundary.

For the simulation of crack propagation, most authors apply linear elastic fracture mechanics (LEFM), in line with Kreyns et al. (1976). By fitting the experimental data of Wood (1972), they advocated that the crack velocities could be related to the fourth power on the stress intensity factor K_I ,

$$\frac{da}{dt} = C \cdot K_I^4 \quad (144)$$

where a is the crack length and C is a constant. The crack intensity factor was shown to be controlled by the elastic stress field at a flaw tip as described by K_I , rather than the nominal applied stress:

$$K_I = \sigma \sqrt{a} Y \quad (145)$$

where σ represents the nominal hoop stress and the factor Y incorporates a correction factor to account for the finite width of a defect-bearing component. Nevertheless, Kreyns et al. (1976) pointed out that small scale plasticity will occur near the crack tip, in a cone with radius r_p :

$$r_p = \frac{1}{\sqrt{6\pi}} \left(\frac{K_I}{\sigma_y} \right)^2 \quad (146)$$

where σ_y corresponds to the yield stress, and $K_I = \sigma \sqrt{a_{eff}} Y$, which results in an effective crack length:

$$a_{eff} = a + r_p \quad (147)$$

and the effective correction factor $Y_{eff} = Y \sqrt{\frac{a_{eff}}{a}}$ becomes

$$Y_{eff} = \frac{Y}{\sqrt{1 - \left(\frac{\sigma}{\sigma_y} \right)^2 \left(\frac{Y^2}{6\pi} \right)}} \quad (148)$$

Anderson (1995) provided a general correction factor so that K_I can be expressed more generally

$$K_I = \frac{pR}{t} \sqrt{\frac{\pi a}{Q}} F \left(\frac{a}{2c}, \frac{a}{t}, \frac{R}{t} \right) \quad (149)$$

where p is the internal pressure on the tube (MPa), R the mean tube radius, t the tube wall thickness, Q the shape factor for an elliptic crack

$$Q = 1 + 1.464 \left(\frac{a}{c} \right)^{1.65} \quad (150)$$

c is the half length of the crack, and F is a boundary correction factor that depends on the shape of the initial crack formed at the inner cladding surface. Park et al. (2008) applied an expression for F within the range of $5 \leq R/t \leq 20$, $2c/a \leq 12$ and $a/t \leq 0.8$:

$$F = 1.12 + 0.053\xi + 0.0055\xi^2 + (1 + 0.02\xi + 0.019\xi^2) \frac{20 - \frac{R}{t}}{1,400} \quad (151)$$

where $\xi = \frac{a}{t} \frac{a}{2c}$. The K_{ISCC} value provided by Park et al. was $3.3 \text{ MPa m}^{0.5}$ and $4.8 \text{ MPa m}^{0.5}$ for stress relieved and recrystallized Zircaloy-4, respectively.

Zhou et al. (2005) replaced the constant C in Eq. (144) by a function of the iodine concentration and an Arrhenius-type temperature dependency. More importantly, however, they also involved the pellet-cladding contact pressure in the estimation of the stress intensity factor. The local effect of the frictional shear forces is accounted for by adopting the Coulomb friction model, according to which the friction force is proportional with the contact pressure. The extension of Zhou et al. is in line with recent findings of Michel et al. (2008). Based on two-dimensional and three-dimensional finite element computations, they showed that the tangential stress concentration in the cladding is proportional to the shear loading transmitted at the pellet-clad interface. As a result, the peak hoop stress at the inner surface of the cladding depends on the interfacial shear stress and the uniform loading in the hoop direction. Nevertheless, the simulations did not account for cladding anisotropy, neither for stress relaxation.

Stress relaxation was accounted for in an empirical manner by Mattas et al. (1979). They assumed the chemical (intergranular) crack growth rate to have an initial value and to decrease exponentially as the crack depth increases. Chemical crack growth was postulated to continue until a critical stress intensity for cleavage and fluting was achieved, at which point intragranular cleavage initiated until failure.

As pointed out by Rousselier et al. (2003), stress relaxation and the ensuing crack arrest is necessary to explain a so-called discontinuity observed during ramp experiments: depending on the maximum power of the fuel rod, either a through crack is obtained within maximum ten minutes or the SCC damage is limited to a few microns, even after hours at the maximum power. This discontinuous behavior was observed above the SCC initiation threshold of about 300 MPa in Zircaloy-4 (Schuster and Lemaignan 1992). Rousselier et al. attributed this to the stress relaxation and to the fact that the intergranular crack could leave the stress concentration zone at the crack tip. Crack arrest was postulated to occur when at the same time the stress intensity factor would be below a certain threshold ($K_I \leq K_{Ia}$) and the stress intensity factor would decrease. However, quantitative information cannot be directly inferred from their analysis, since the critical stress corresponding to K_{Ia} should depend on the material (stress relieved versus recrystallized), the irradiation as well as the loading history. Furthermore, the LEFM should not be applied without corrections for the visco-plastic behavior and finally, because of the local inhomogeneities of the material at the scale of the crack one should apply local rather than global criteria such as $K_I \leq K_{Ia}$.

With the advent of improved computers and software on one hand, and more detailed experimental data on the other hand, more detailed models are being developed at various scales. At the electronic and atomic scale, first principle computations should enable analyzing the individual effect of impurities such as iodine on the binding energies, in much the same way as Xin et al. (2009) have studied the point defects properties and their interactions with Nb in Zr or Kaji et al. (2002) analyzed the clustering of Ni in Fe. By means of finite element computations on the level of crystallographic grains, Rousselier et al. suggest avoiding the limitations associated with LEFM for crack initiation and propagation. Because of the excessive computation time and the lack of precise data of some model parameters, their model is not applicable in fuel performance codes but should enable analyzing the effect of corrosive fission products on the intergranular damage by coupling the mechanical problem with a diffusion problem. A similar tool has already been developed by Musienko et al. (2009), albeit that the corrosive environment parameters are accounted for by a phenomenological approach, that is, via an effective diffusion coefficient. At the meso-scopic scale, Kaji et al. developed a two-dimensional model for SCC growth, in order to analyze qualitatively the effect of load (normal versus shear stress) and grain boundary corrosion on the branching aspect of crack growth. The macroscopic models are mostly based on finite element simulations (Marchal et al. 2009; Michel et al. 2008). These tools provide deeper insight and qualitative information about the various parameters affecting PCI as explained above. Nevertheless, these models are not yet capable of replacing the simplified one-dimensional models implemented in fuel performance codes, despite the improvements of computers and software. Marchal et al. (2009) are trying to develop analytical “enrichments” for one-dimensional models in fuel performance codes based on the two-dimensional models. The stochastic nature of cracking along with the complex evolution of material properties and boundary conditions during irradiation are the most important difficulties to be tackled.

6.2.3 Outside-In Cracking Caused by Power Ramps

High burnup fuel rods in LWRs are characterized by the absence of a clearance between the pellets and their metallic containment. During power ramp tests with high burnup BWR rods, a failure mechanism therefore occurred from the cladding outside toward the inner surface of the zircaloy (Shimada et al. 2004) as opposed to standard PCI–SCC as discussed above. Post-irradiation examination revealed that the process started an axial split with cracking of radial hydrides that had formed during the power ramp test, followed by a step-by-step cracking of hydrides at the crack tip. The process bears similarities with secondary hydride failures discussed above. The temperature gradient along the cladding and the stress due to the ramp test precipitate radial hydrides in the outer surface of the tube. These hydrides can crack under the influence of stress caused by PCMI and progressing toward the inner tube surface. The main difference with secondary hydride failures that start on the inner surface is that hydrogen is already absorbed at the outer surface due to clad oxidation during normal operation.

6.3 Pellet-Coolant Interaction

Failure of a fuel rod has a probability of between 10^{-4} and 10^{-6} per year. It can be caused by a design fault in the cladding, by fretting of debris or rod to grid fretting, by pellet-cladding mechanical interaction, or stress corrosion cracking. Operational experience during the last

■ Figure 32

Schematic of physical/chemical processes in defective fuel. Sources of hydrogen and gas-phase transport in the element (upper figure), and cross section of a defective element showing interstitial oxygen diffusion in the solid fuel matrix and gas-phase transport of hydrogen/steam in the fuel cracks (lower figure) (Higgs et al. 2007) © Elsevier, 2007, reprinted with permission

10 years has reduced the failure probability significantly, and rod to grid fretting is now the main cause for failure.

In case of failure of the fuel rod cladding, interaction of steam with the pellet will take place. As discussed by Higgs et al. (2007), this is a complex process, as depicted schematically in ► Fig. 32. After a breach in the cladding occurs, hot steam will enter the fuel rod, where it will react with the Zircaloy (152) producing hydrogen:

The ratio of the partial pressures of H₂ and H₂O (Eq. 152) will control the oxygen potential of the gap atmosphere. At the same time the fuel pellet surface will be oxidized

■ Figure 33

UO_2 oxidation near a primary cladding defect, showing the effects at the pellet surface and in the pellet cracks. (Higgs et al. 2007) © Elsevier, 2007, reprinted with permission

where the value of x is principally controlled by the oxygen potential of the gap gas, as the hydrogen production by thermal oxidation of the fuel in steam is small compared with that due to cladding corrosion (Olander et al. 1999). Similarly the gap gas will diffuse into the hotter regions of open cracks of the fuel, also establishing equilibrium with the solid phase around the crack region (► Fig. 33). The increase of the O/M ratio in the rim and crack regions of the pellet will lead to diffusion of oxygen into the fuel. Considering the temperature regime for LWR fuel and the high fuel density, thermodiffusion of interstitials is considered to be dominant for the redistribution of oxygen in a temperature gradient (Soret effect).

Une et al. (1995) reported post-irradiation examinations of UO_2 pellets from defected fuel Zircaloy-clad BWR fuel rods that had small leaks along both pellet diametral and fuel rod axial directions. They reported that the fuel oxidized to hyperstoichiometric UO_{2+x} , the fuel oxidation significantly depending on the defect size and distance from the defect. The pellet volume-averaged O/M ratio at various axial locations were in the range of 2.02–2.06, whereas higher O/M ratios were detected at the fuel periphery, which decreased toward the pellet center, except for the specimen near the secondary defect at the rod bottom having the opposite O/M distribution. However, Olander et al. (1999) claim that there is no conclusive evidence that oxidation to such O/M ratios can occur with steam during the incubation stage following initial cladding perforation. They argue that experimental and theoretical evidence indicate that UO_2 is resistant to oxidation by irradiated steam as long as even a minor percentage of hydrogen is present. They suggest that direct contact with liquid coolant containing dissolved O_2 can produce highly hyperstoichiometric uranium oxides, or even oxidation with storage pool water.

As the oxidized fuel has a much lower thermal conductivity than stoichiometric fuel (see ► Fig. 6) and a lower melting temperature, the coolant-cladding interaction can have a significant impact on the fuel thermal performance. The higher fuel temperature could lead to increased fission gas release. Une et al. (1995) indeed found a remarkable difference in Xe release between the defective and sound fuels. Another consequence can be local fuel melting, as has been observed for CANDU fuel by Lewis et al. (2004).

6.4 Loss-of-Coolant Accidents

6.4.1 Sequence of Events during a LOCA

A loss-of-coolant accident (LOCA) in a water cooled reactor consists of a large break of the coolant primary system and consequent loss of core cooling capacity. A LOCA is a design basis accident, that is, an accident that the plant design must account and accommodate for in terms of ensuring that a core coolable configuration is maintained. Post-LOCA coolability is achieved by an immediate reactor scram, that is, a rapid insertion of control rods in the core, which ends the fission power production in the nuclear fuel, and by the activation of an emergency core cooling system (ECCS) that enters into function upon depressurization, within relatively short time after start of the transient. As schematically shown in  Fig. 34, a typical LOCA sequence in a light water reactor (LWR) consists of the following phases:

1. Depressurization (blow down) of the primary system, accompanied by an automatic reactor scram. During this phase the fuel temperature may oscillate depending on position, timing of the power reduction, and timing of the depressurization. The cladding temperature may even decrease since the water still has enough cooling capacity and because the water temperature is decreasing as pressure decreases.
2. Heat up of the core caused by the remaining heat generation in the fuel (stored and decay heat) and by the loss of water inventory. The decay heat will continue to be active despite shutdown of the fission power. Some amount of water remains in the lower portion of the core, whereas steam prevails at middle and high core elevation, leading to a more pronounced heat-up rate in the upper regions of the core. The heat-up rate varies with plant design, fuel design, and operating power at the time of the LOCA. Normally, the fuel-cladding

 **Figure 34**
A schematic representation of a LOCA sequence

temperature increases at moderate rate, approximately some few degrees per second in the earlier phase of the temperature escalation. When the temperature exceeds 600°C , the cladding becomes more and more prone to plastic deformation and under the effect of the rod inner pressure – which is appreciably larger than in the depressurized reactor vessel – it starts deforming and balloon in the space between the fuel assembly grid spacers. If the ballooning exceeds a certain size, the fuel rod cladding will burst open, breaking the first barrier to radiation containment. In addition, the zircaloy cladding undergoes phase transitions from a so-called α phase to a β phase at temperature exceeding 900°C (cf. 🔍 Sect. 4.2), although one should consider that the transition temperature is to some extent affected by the amount of hydrogen contained in the metal cladding as well as the heating rate.

3. The cladding temperature continues to increase but at gradually lower rate due to the increasing radiant and convective heat transfer, exhibiting a relatively flat temperature trend for some period of time normally lasting for a few minutes. Under the ECCS effect, the cladding temperature trend is then reversed and after a period of gradual temperature decrease, the cladding is finally quenched by the ECCS water rising in the core.

6.4.2 Main Characteristics of a LOCA Failure

Important phenomena occur in the fuel as the heat-up progresses. One is the already mentioned ballooning and burst, which normally occurs in the cladding temperature range $600\text{--}800^{\circ}\text{C}$, depending on the rod inner pressure. In fuel performance codes, usually a one-dimensional mechanical model is applied for the radial cladding deformation. For dealing with large high-temperature deformation (i.e., ballooning), typically during a LOCA-type accident, (73) is applied. As described in 🔍 Sect. 4.6.2, the strain is calculated for the α and β phases separately and weighted Eq. (74).

A number of experimental studies have been conducted in the past to verify that a ballooned fuel assembly remains coolable in spite of the reduced rod-to-rod spacing. The conclusions of these studies, which were conducted decades ago and which evidenced that ballooned assemblies remain coolable, have not been challenged in subsequent times. Hence, the ballooning as such does not constitute a limitation in the current LOCA safety assessment.

Another important phenomenon is the release of fission products from the fuel into the primary system and hence inside the reactor containment. The radiological consequences are assessed through conservative estimates, which may entail assumptions such as complete release of the plenum fission gas and of the inter-granular fission products inventory at the time of the accident, as well as complete fission product release from the fuel region exceeding a certain temperature threshold.

The major concern from the fuel safety criteria viewpoint is the rapid cladding oxidation taking place when the cladding is exposed to high temperature and steam environment, as it occurs in a LOCA.

6.4.3 Current LOCA Safety Criteria

LOCA Criterion Based on Zero-Ductility

In the high-temperature range ($>800^{\circ}\text{C}$), the cladding oxidation kinetics increases dramatically with temperature, typically doubling for a temperature increase of 20°C . This has the

significant consequence that hydrogen is generated in the core due to the zirconium–water reaction (152). One should also consider that the zirconium–water reaction is exothermic and has a heat release of 580 kJ/mol (Powers 2000), which adds to the cladding heat-up caused by the fuel decay heat.

It is known that the zircaloy cladding becomes brittle when subjected to high temperature oxidation in steam environment, mainly due to the hydrogen that remains entrained in the metal itself during the high-temperature oxidation process. This increased cladding brittleness has a major impact on the failure criteria. As stated in the US code of Federal Regulations issued in 1971 “General Design Criteria for Nuclear Power Plants,” US code of Federal Regulations, Title 10, Part 50, Appendix A, 1971, “the cladding temperature transient is terminated at a time when the core geometry is still amenable to cooling, and before the cladding is so embrittled as to fail during or after quenching.” Atomic Energy Commission Rule-making Hearing, Opinion of the Commission, Docket RM50-1, 1973. Since it was deemed difficult or impossible to quantify the type and magnitude of the stress imposed to the cladding during or after quenching (especially in coincidence of, e.g., a seismic event), the US Atomic Energy Commission stated their “belief that retention of ductility in the zircaloy is the best guarantee of its remaining intact during the hypothetical LOCA.” Consistent with the above, the current LOCA safety limits are in most countries based on ductility tests. These are performed by first subjecting tube test specimens to two-side steam oxidation at various temperature levels and for varying duration. Two-side oxidation is used because the cladding is assumed to have ballooned and burst open, giving steam access also to the tube interior. Two-side oxidation provides maximum cladding exposure to steam and is a conservative test configuration, since it represents the most severe oxidation condition.

Upon completion of the high-temperature oxidation phase, the specimen residual ductility is determined by a ring compression test. The results of such ring compression tests for the various specimens are separated in two categories, that is, those showing some residual ductility and those exhibiting brittleness or “zero ductility.” As shown by Hobson and Rittenhouse already in 1972 (Vitanza 2006), the brittle category would expectedly consist of those specimens that experienced longer exposures and/or higher temperature during steam oxidation. When plotted on a oxidation time vs. oxidation temperature diagram (i.e., on a $\text{Log}(\text{time})$ vs. $1/T$ diagram), the Hobson and Rittenhouse ductile and brittle data were separated by a line, which approximately corresponded to a 17% cladding wall oxidation (or 17% ECR, equivalent cladding reacted), when oxidation was calculated with the Baker–Just correlation (see [Sect. 4.6.1](#)) as two-side oxidation (Vitanza 2006). Hence, the Baker–Just 17% ECR was adopted as general LOCA embrittlement criterion, together with the additional requirement that the cladding temperature should not exceed 1204°C, as there was evidence of substantial rapid embrittlement beyond that temperature level. The embrittlement is explained by solid–solution hardening of transformed-beta phase at high oxygen concentrations that are characteristic of oxidation at the high temperature (Chung 2005). Furthermore, prevention of runaway oxidation was another factor in limiting the peak cladding temperature to 1204°C, above which heat generation from metal–water reaction becomes excessive and an autocatalytic type of situation can occur (Chung 2005).

In fact the safety criteria are stated as five requirements dealing with the calculated performance of the cooling system under the most severe loss-of-coolant accident conditions. The first two are the maximum of 17% ECR and 1204°C peak cladding temperature mentioned above. The third requirement addresses the maximum hydrogen generation, the total amount of which shall not exceed 1% of the hypothetical amount generated by the reaction of all the metal in

the surrounding fuel. Finally, the last two requirements are related to the core cooling. More precisely, the calculated changes in core geometry shall leave the core amenable to cooling and after any operation of the ECCS, the core temperature shall be maintained at an acceptable low value and decay heat removed for the extended period of time required by long-lived radioactivity.

The so-called 17% ECR criterion, established in the early 1970s, is still applied today, although with small variations in some cases. Regarding actual applications in LOCA assessments, the following points should be considered:

1. The 17% ECR limit is a time-temperature limit, not an oxidation limit as such. The criterion precisely states that the 17% ECR must be calculated with the Baker–Just (B–J) correlation. When this is done, the 17% limit is nothing more than a straight line in a time-temperature domain.
2. Unfortunately, the criterion is often misinterpreted, and other correlations are used instead of the B–J correlation. In some cases, for instance, the Cathcart–Powel (C–P) correlation (see ► Sect. 4.6.1) is used in licensing evaluations, with the motivation that it is a better correlation to predict oxidation. While this might well be the case, the 17% limit is not an oxidation limit, but a ductile-to-brittle limit, which happens to coincide with the B–J calculated 17% ECR. Fortunately, the difference between the C–P and the B–J correlation is not very large, as ► Fig. 11 shows. However, this apparently minor change does imply a loss of a $\sim 50^{\circ}\text{C}$ margin in the LOCA assessment.
3. Occasionally, other researchers express experimental ductility data as function of “measured ECR” instead of the calculated one, claiming that the measured value would provide a more realistic reference than the B–J calculated ECR. In reality, a ductility limit expressed vs. measured ECR is meaningless for a LOCA assessment if it is not supported by a sufficiently precise knowledge of the oxidation dependence of time and temperature.
4. Since the LOCA ductility database is founded on two-side oxidation tests, ECR LOCA calculations shall be made with a two-side oxidation assumption. This may be a conservative assumption because access of steam to the interior of a fuel rod may be limited, especially in regions away from the ballooning regions and especially at high burnup, when the pellet-to-cladding gap is very small. However, a sufficiently comprehensive characterization of ID vs. OD corrosion at various axial positions and at realistic conditions does not exist at present. Further, most LOCA ductility assessments assume that the cladding zero-ductility limit should not be encroached anywhere along the cladding. Hence there is no basis for taking credit for cladding being subjected to one-side oxidation only “somewhere” along the fuel rod length.

The zero-ductility criterion is derived from steam oxidation experiments normally carried out at constant temperature. The applicability to a generic temperature transient has been discussed above. However, zero-ductility is not a straightforward cladding characteristic as its definition may depend on several details of the experimental set up used for measuring the residual ductility and on the method for exactly determining it. Important question marks can also be raised on the way it should be applied, as it will be discussed below.

LOCA Criterion Based on Integral Quench Tests

The experimental basis for the LOCA criteria in Japan consists of quench tests conducted on fuel rod simulators made of cladding tube segments filled with alumina pellets. These tests were performed at JAERI (now JAEA) in the 1980s (Uetsuka et al. 1983). The cladding tubes were

■ Figure 35

JAERI quench test database on as-received Zircaloy-4 tubes subjected to high-temperature oxidation and quench, under full constraint condition (Uetsuka et al. 1983)

ballooned, ruptured, subjected to high-temperature two-side oxidation, and then quenched. During quenching there was full constraint, that is, the tubes were held at both ends in order to prevent axial contraction during cooling. The full constraint was used as the bounding case for the actual fuel assembly condition, since a reliable assessment of fuel-grid interaction and consequent loading was difficult to make at that time.

Approximately 50 experiments were carried out on nonirradiated Zry-4 cladding tubes, which served as basis for the Japanese LOCA criteria. The results were divided in two categories, depending on whether the tube had survived or failed during the quenching. ➤ Figure 35 provides a plot of the experimental results, showing the data points for the failed and non-failed tubes on a time vs. temperature diagram. As one can observe, the Baker-Just 15% ECR line represents a conservative rendition of the results. As most phenomena under LOCA conditions, including rupture, secondary hydriding from inner surface and axial loading during the quench, are taken into account in the quench tests, the 15% ECR criteria was adopted as the LOCA failure criterion – and hence coolability criterion – in Japan (Uetsuka et al. 1983).

As already mentioned, the JAEA integral tests constitute an as-close-as possible representation of an actual fuel rod and of all the phenomena that actually incur during a LOCA. In fact, the fuel rod simulator is subjected to heat-up, ballooning and burst, high-temperature oxidation,

and quenching as it would be in an actual LOCA. In this sense, it appears to be much closer to a realistic simulation of all LOCA phenomena than the ductility tests. This is particularly true for what concerns ballooning, a phenomenon that is incorporated in the integral quench testing while it still represents a question mark for the applicability of the zero-ductility criterion. Setting the coolability limit in correspondence of the fuel failure during quenching ensures conservatism in this approach, hence providing a certain (although unquantified) degree of safety margin. However, an aspect that requires attention is the type and level of stress that can arise in the cladding during quenching. While full axial constraint certainly represents a conservative assumption on axial stress, questions can be raised as to the lack of transversal forces acting on the cladding in the JAEA testing.

6.4.4 Extension to High Burnup Fuel

Zero-Ductility Limit at High Burnup

In an overview of the experimental database performed in 2005 (Vitanza 2006) it was shown that the zero-ductility LOCA limit for high burnup fuel is affected by the amount of corrosion experienced by the fuel cladding during service. In particular, it was found that the zero-ductility limit was decreasing proportionally to the amount of hydrogen picked up by the cladding as a consequence of corrosion. Consistently with the available database, the ECR limit (at 135°C) could be expressed as follows:

$$\text{ECR}(B - J) = 17\% \left[1 - \alpha \frac{H}{1,000} \right] \quad (154)$$

(up to $H = 600$ ppm, stable for $H > 600$ ppm) where H is the hydrogen content in the cladding prior to the high-temperature transient, in ppm. As shown in  Fig. 36, the parameter α was found to vary between 0.5 and 1 depending on the type of test performed. In acknowledgment of the results obtained at JAEA, which showed that the ECR decreased up to 600 ppm and stabilized beyond that (see  Fig. 37), the ECR was assumed to stabilize beyond $H=600$ ppm at a level

$$\text{ECR}(B - J) = 17\%[1 - \alpha \cdot 0.6] \quad (155)$$

This implies that the LOCA zero-ductility limit at high burnup would decrease from 17% to about 7% for the case $\alpha = 1$.

In a subsequent USNRC report issued in 2008 (Billone et al. 2008), a similar linear decrease of the zero-ductility ECR was proposed, but with a more pronounced slope as compared with (154). The results are shown in  Fig. 38. As one can notice, there is no cut for hydrogen content beyond 600 ppm in this case. An in-depth analysis of the database considered in that report is beyond the scope of this chapter. However, it is worth noting that there are only two data points for hydrogen beyond 100 ppm, and that this is indeed a too scarce database.

In particular, much data at high hydrogen content would be needed to justify the continuous decrease of the zero-ductility limit all the way down to $\text{ECR} = 0$, a limit that would imply that fuel with hydrogen content beyond 700 ppm would simply not be allowed to operate in a power reactor. The situation would be even worse if the limit is applied considering local hydrogen content instead of average, a point that is not clarified in Billone et al. (2008).

Figure 36

Decrease of the LOCA ECR limit as a function of hydrogen content in the cladding prior to LOCA, as obtained from different types of experiments. All data have been normalized to 17% for zero hydrogen content. The two solid lines are predictions obtained by setting $\alpha = 0$ and $\alpha = 1$ in Eq. (154)

Figure 37

Decrease of LOCA ECR limit as a function of hydrogen content in the cladding prior to LOCA, as obtained from different types of experiments at JAEA

LOCA High Burnup Limit from Integral Quench Tests

Integral tests in the high burnup range have been performed at JAEA. Fuel rods retrieved from power plants were transferred to hot cells and cut in order to extract a test segment at a pre-determined position. This was defueled and then refilled with alumina pellets, pressurized to a predetermined pressure and sealed by end plugs. The test segment was then transferred to the experimental equipment in order to be subjected to the integral LOCA sequence, that is, heat-up, ballooning and rupture, high temperature oxidation, and quenching.

Quenching was intended to be performed in the presence of an axial loading of approximately 500 N, which in JAEA's estimate represents an upper limit for the force expected to be exerted on an actual fuel rod during quenching. In some cases, however, it was difficult to maintain the load, such that some of the tests were in fact carried out with reduced or no loading.

■ Figure 38

Decrease of LOCA ECR limit as a function of hydrogen content in the cladding prior to LOCA, as obtained from different types of experiments published by NUREG (Billone et al. 2008)

Different types of PWR cladding and one BWR cladding were tested and are listed in ► Table 6. The fuel burnup in the region corresponding to the cladding test segment ranged between 66 and 76 MWd/kg. The corrosion layer at power reactor discharge was low for the M5 cladding (6–7 μm), while it varied from 32 to 79 μm for the other PWR cladding segments and from 24 to 30 μm for the two BWR segments. Correspondingly, the hydrogen content in the cladding prior to the LOCA test was ~ 70 ppm for the M5 cladding and in the range ~ 200 –850 ppm in the other cases.

The oxidation temperature reached almost 1200°C in all cases, while time ranged from 130 to 280 s except in one case in which it was 719 s. In the latter case, the B–J calculated high-temperature oxidation was large and corresponding to an ECR = 35.6%. The axial loading during quench was 518–530 N in five tests, ~ 200 –400 N in three tests. No loading was applied in two cases.

The test segment with highest oxidation (ECR = 35.6%) is the only one that fractured upon quenching. None of the other tests resulted in segment fracture, even if the B–J ECR was close to or higher than 17% B–J ECR.

The outcome of the JAEA results obtained so far are summarized in ► Fig. 39. As one can observe, the conclusion of this type of testing is that cladding fracturing does not occur regardless of the initial hydrogen content, unless a very high ECR is achieved. In other words, there would be no need to modify the current 17% (or 15%) ECR limit, as this would remain valid also for high burnup fuel, if the JAEA methodology is adopted. This is quite a different conclusion than the one reached with the zero-ductility approach, which would imply a strong decrease of the ECR limit with initial hydrogen content. This different position is in fact a most important consideration regarding the methodology to be adopted in LOCA tests, an issue that the nuclear community needs to address and resolve in principle.

Table 6
LOCA test results

Test rod ID	LMDA1R	LMDA2R	LMF11	LMF12	LNDA1	LZIR1R	LZIR2R	LZIR3R	LZRT1	LZRT2

^a The value in bracket is B-J calculated ECR for non-deformed cladding, whereas the other value in the table is calculated considering the wall thinning in the ballooning region (circumferential strain is also given in the table).

■ Figure 39

Outcome of the JAEA integral quench test. The results so far show that the 17% ECR criterion holds also at high burnup. This is opposite to the results obtained from ductility tests (see ► Fig. 37)

6.5 Reactivity-Initiated Accidents

6.5.1 Sequence of Events during a RIA

The reactivity-initiated accident (RIA) is another design basis accident for LWRs, postulated to occur with a very low probability albeit with serious consequences when not appropriately accounted for in the reactor design. The RIA involves the unexpected removal of a control element from the reactor core, resulting in a prompt criticality of the reactor characterized by a rapid power excursion on a time scale of tens of milliseconds in neighboring fuel elements. The power increase in the rods adjacent to the ejected control rods is significant but remains limited, thanks to the natural occurrence of the Doppler effect caused by the temperature increase in the fuel. Afterward, the power is reduced to zero by insertion of fault-free control rods triggered by the reactor criticality.

Among the various scenarios considered for a RIA, the most penalizing in a PWR consists of a control rod ejection at hot standby conditions, and a control rod drop accident at cold zero power (CZP) conditions in a BWR. The form and duration of the power peak depend on the scenario, the fuel and reactor design as well as the condition of the fuel. State-of-the-art three-dimensional neutron kinetics codes indicate that the width of the power pulse is in the range of 25–75 ms in fuel with a burnup exceeding 40 MWd/kgHM (Meyer 1996).

During the pulse, one can distinguish three phases in the fuel rod behavior. The first phase of the RIA is characterized by the quasi-adiabatic temperature increase in the fuel, accompanied by its thermal expansion and the fission gas swelling. This results in a cladding temperature increase at a rate on the order of 1000°C/s and a multiaxial loading on the cladding, driven by the fuel displacement. The hoop strain rate is on the order of 1/s (Federici et al. 2001), being four to five orders of magnitude larger than rate during a normal power ramp of about 10 kW/m per

minute. The clad load is multiaxial: the axial to tangential strain ranges between 0 and 1. The purely tangential strain is only achieved when the friction between fuel and cladding is infinite, whereas the equivalent deformation in axial and tangential direction is obtained when there is no slip between both components. During the first phase of the RIA, the cladding temperature remains moderate, typically below 600°C. Therefore the cladding can fail due to PCMI, depending on the cladding condition properties (irradiation damage, oxide thickness, hydride concentration and orientation, etc.). In some cases the cladding oxide underwent spalling off, causing a local cladding cooling along with a clad ovalization on nonuniform deformation.

During the second phase of the RIA, the cladding temperature continues rising because of the energy generated by the fuel, and can lead to departure of nucleate boiling (DNB). Under these conditions, the cladding temperature could remain above 1,000–1,200 K for up to 10–15 s. During the temperature increase the clad stiffness is strongly impaired, while the inner gas pressure of the rod increases due to gas release and the temperature increase. A local deformation and clad rupture may result.

During the third stage of the RIA, the cladding is submitted to a rewetting or quenching, which may cause a fragile rupture, especially when clad oxidation is important. During this cooling, hydrides that were dissolved at high temperature may precipitate again under influence of the stress in the radial direction. Brittle radial hydrides that are perpendicular to the main (hoop) stress contribute to cladding fragilization, although clad rupture caused by radial hydrides during the quenching phase of a RIA has never been reported.

During the fourth and last stage of a RIA, fuel dispersal can occur. Indeed, when the energy deposition is high enough, fuel melting accompanied by excessive fuel swelling could cause clad failure by overheating or overstraining. When dispersed into the coolant upon clad failure, the hot fuel may cause a pressure pulse in the water due to vaporization, potentially damaging neighboring assemblies or other core components.

6.5.2 Main Characteristics of RIA Failures

Among the four failures modes described in the sequence of events, there are two dominant types of fuel rod failures during a RIA. The first deals with a typical PCMI failure and is predominant for fuel rods irradiated to an average burnup beyond 30–40 MWd/kgHM because of gap closure and clad fragilization. The second type of failure is more typical for fuel rods with a lower burnup level and is caused by gaseous pressure at high temperature during the post-DNB phase. However, the post-DNB phase and the phenomena occurring after rupture have not yet been reproduced properly.

Most research is directed toward the first failure type because of the tendency to increase the average discharge burnup levels for economic reasons, and because this is considered to be the most severe criterion for high burnup rods. The main factors affecting the PCMI failure type are the following:

- The gap size
- The burnup (because of the clad fragilization caused by irradiation damage, oxidation, and hydrogen pickup)
- The friction coefficient (friction will distribute the deformation, hence reduce the failure propensity)

- The width and height of the power pulse (large pulse widths enable the clad temperature to raise along with the stress, reducing the risk of fragile rupture in the first phase of the RIA).

The fragile failure of the cladding during the first phase of the RIA takes place at a hoop strain on the order of 1%, and takes place in two steps. The first step consists of radial crack nucleation in the hydrogen-rich outer (fragile) cladding layer, followed by its propagation in a ductile manner toward the cladding inner surface until the local deformation exceeds the rupture limit, causing cleavage in a shear band oriented 45° away from the radial and tangential directions. There seems to be a transition zone between the fragile and ductile part due to pseudo-cleavage, which is more affected by the hydrogen concentration gradient than by the temperature gradient (Hermann et al. 2007). During the second phase of the failure, a few of the radial cracks will propagate axially, causing long splits along the hydrogen-rich zones (Fuketa et al. 1997).

6.5.3 RIA Safety Criteria

Acceptance criteria for fuel behavior during a RIA were established by the US NRC based on early tests in pulse reactors (US-NRC 1981) and used worldwide, albeit sometimes in a slightly modified form. The first criterion defines a limit on the radial average fuel enthalpy at 1,172 J/g (280 cal/g) to ensure core coolability and reactor pressure vessel integrity by preventing fuel melting, the ensuing fuel expulsion, and violent fuel-coolant interaction and generation of pressure pulses. Nevertheless, a revised criterion of 963 J/g (230 cal/g) has been recommended in 1980 (Hollasky et al. 2000; MacDonald et al. 1980) since some tests also indicated that a fuel rod subject to a radial average peak fuel enthalpy of this amount would be severely damaged, lose its original geometry, and impair post-accident cooling. In Japan, the same threshold energy is imposed by the regulatory body to prevent melting, fragmentation, and fuel dispersal (Fuketa et al. 1997), while in France it is 942 J/g (225 cal/g) and 837 J/g (200 cal/g) for fresh and irradiated fuel respectively (Chung and Kassner 1998). A second criterion aims at limiting the radiological consequences of escaped fission products in the event of fuel rod failure and fixed the upper limit for the average fuel enthalpy at 712 J/g (170 cal/g).

More recent tests on pre-irradiated fuel revealed clad failure at enthalpies below 712 J/g in high burnup rods. The prevalent safety criteria have therefore been questioned, and it was realized that they do not account for cladding embrittlement along with gap closure. This has prompted a new series of experiments. To date, a total of 78 RIA tests on high burnup LWR fuel rods, pre-irradiated in commercial reactors, have been carried out in various test reactors, as summarized in  Table 7. The integral tests in pulse reactors provide valuable information about the fuel behavior under RIA conditions. However, they are costly and do not enable the assessment of the effects of particular parameters. To this end, complementary separate-effect tests are made out-of-pile (Cazalis et al. 2005; Kuroda et al. 2001; Le Saux 2008; Le Saux et al. 2008; Link et al. 1998), enabling the development of models. Nevertheless, correct extrapolation of the results and models of out-of-pile tests to in-pile RIA tests is delicate because the test conditions (e.g., sample geometry, deformation rate, and temperature) are not always fully representative.

The prediction of fuel rod failure during a RIA requires the use of a computer code that accounts for the various aspects of the fuel behavior. In order to guarantee acceptable calculation times, however, only simplified models for the clad rupture can be afforded, rather than complex

■ Table 7

Overview of RIA simulation tests in the CANRI, NSRR, IGR, and BIGR reactors

mechanistic models. On the basis of the experimental results and main characteristics, several RIA rupture criteria have been proposed and are adopted in fuel performance codes. The models are either based on the rupture strain, or in terms of a rupture strain energy density (SED). The models based on rupture strain postulate clad failure when

$$\varepsilon_{\theta}^p \geq \varepsilon_{\theta}^*(z, t) \dot{\varepsilon}_{\theta}^p(z, t) > 0 \quad (156)$$

where ε_{θ}^p and $\dot{\varepsilon}_{\theta}^p$ represent the radially averaged clad hoop strain and strain rate, respectively. The uniform hoop elongation is often selected for two reasons. Firstly, the largest strains due to PCMI are in the tangential direction. Secondly, the true failure strain is somewhere between uniform elongation and total elongation (includes both uniform and localized strain) at failure. Geelhood et al. (2004) have implemented such a uniform strain-based failure model in the FRAPTRAN code. The empirical correlation was derived from biaxial burst tests in addition to uniaxial tension tests on irradiated Zircaloy, and is a function of the temperature and excess hydrogen in the cladding (i.e., the quantity of hydrogen above the solubility limit). Therefore, they have had to apply a correction factor because of the nonrepresentative stress conditions. They also implemented a new yield stress correlation, whereby the plastic strain hardening component is dependent on both the temperature and the fast neutron fluence (representing irradiation damage) and has been fitted on the basis of the same set of experiments. As a result their failure predictions account for the temperature, the irradiation damage, the strain rate, and the hydrogen content. In a similar manner, Jernkvist (2006) proposed more recently an empirical correlation for ε_{θ}^p for recrystallized Zry-2 and stress-relieved Zry-4 on the basis of

more than 200 out-of-pile mechanical property tests:

$$\varepsilon_{\theta}^* = \frac{3 \cdot \varepsilon_{\theta}^0 \cdot S \cdot f_1 \cdot f_2 \cdot f_3}{f_1 \cdot f_2 + f_1 \cdot f_3 + f_2 \cdot f_3} \quad (157)$$

where ε_{θ}^0 is the plastic strain to failure of as-fabricated cladding at low strain rate, S is a ductility reduction factor for clad tubes with spalled oxide layer, responsible for detrimental effects of a nonuniform hydride distribution, and f_1 , f_2 , and f_3 are ductility reduction factors accounting for elevated strain rate, hydrogen-induced embrittlement, and irradiation damage, respectively. The functions have been fitted to the experimental data and are as follows:

$$\varepsilon_{\theta}^0(T) = 2.82 \times 10^{-2} + 1.22 \times 10^{-4} T \quad (158)$$

$$f_1(\dot{\varepsilon}_{\theta}) = \begin{cases} 1.0 & \dot{\varepsilon}_{\theta} < 8.37 \times 10^{-4} \text{ s}^{-1} \\ 0.046 - 0.031 \log_{10} \dot{\varepsilon}_{\theta} & 8.37 \times 10^{-4} \leq \dot{\varepsilon}_{\theta} \leq 1 \text{ s}^{-1} \\ 0.046 & \dot{\varepsilon}_{\theta} > 1 \text{ s}^{-1} \end{cases} \quad (159)$$

$$f_2(c_{\text{Hex}}, T, \dot{\varepsilon}_{\theta}) = 0.01 + 0.99 e^{-\gamma(T, \dot{\varepsilon}_{\theta}) c_{\text{Hex}}} \quad (160)$$

$$\gamma(T, \dot{\varepsilon}_{\theta}) = 6.52 \times 10^{-4} + 2.21 \times 10^{-3} (6 + \log_{10} \dot{\varepsilon}_{\theta}) \left(1 - \tanh \left(\frac{T - 298}{8.5} \right) \right) \quad (161)$$

$$f_3(\phi) = 0.05 + 0.95 e^{-2.89 \times 10^{-24} \phi} \quad (162)$$

The empirical correlation for the rupture hoop strain is valid for temperatures between 20 and 400°C, deformation rates between 5×10^{-5} and 1 s^{-1} , hydrogen concentrations in the range of 0 and 1941 ppm, and fluences between 0 and $12 \times 10^{25} \text{ n} \cdot \text{m}^{-2}$. Jernkvist (2006) implemented this rupture threshold in the SCANAIR-3.2 code that was originally developed at the IRSN in France. It was verified on the basis of integral tests in the CABRI and NSRR pulse reactors. The comparison with the experimental data indicates that the strain-based criterion is conservative, and that the standard deviation of the relative differences between calculated and measured failure strain obtained with the modified SCANAIR-3.2 code is 0.57. A part of the scatter has been attributed to the deviation of the loading conditions of the out-of-pile tests from those of the in-pile tests (tangential and axial loading nearly equal), which required the application of a correction factor to the measured hoop strains.

Desquines et al. (2005) adopted a more physical-based modeling for defining the rupture strain. More precisely, they applied the concept of elastoplastic failure mechanics, in line with Kuroda et al. (2001), and combined this with a probabilistic model for the defect size and the oxide layer thickness (or average hydrogen content) in order to determine the failure probability as a function of the hoop strain at failure, the oxide layer thickness, the temperature, and the height of the fuel rod (Le Saux 2008). Although they had a lack of experimental data at temperatures above 400°C, they applied the rupture criterion in the SCANAIR code at IRSN.

The strain-based failure criterion is conceptually simple, and the correlation can be determined in a rather straightforward manner from total elongation as well as burst strain data. However, these data are not true material properties, and attention must be paid to the impact of the specimen geometry and load biaxiality. Furthermore, the strain-based failure criterion depends on the mechanical loading and temperature history prior to failure. As an alternative, a critical strain energy density (CSED) has been proposed by Rashid et al. (2001) and implemented

in the FALCON code. The measure for the clad to resist failure is formulated as the total mechanical energy (elastic + plastic) per unit volume that can be absorbed by the material before it can fail. The threshold value for SED is derived from the experimental stress-strain curves and is expressed as a function of the fast neutron fluence, temperature, hydrogen concentration, and material type, or alternatively the oxide thickness. A correction factor was applied to account for deviations from the biaxiality of stress during the tests, and it should be underlined that the tests were limited in terms of strain rate ($7 \times 10^{-5} \text{ s}^{-1}$ instead of $1\text{--}5 \text{ s}^{-1}$ for RIA). A similar approach was adopted by Bernaudat and Pupier (2005) and Leclercq et al. (2008) for application in the SCANAIR code applied by EdF, although the CSED limit is expressed as a function of the oxide thickness or the average burnup:

$$\begin{aligned} \text{CSED} &= 95.17 - 4.7653 \cdot \text{OX} + 8.759 \cdot \text{OX}^2 - 5.56 \times 10^{-4} \text{OX}^3 \\ \text{if } \text{OX} &< 54 \text{ } \mu\text{m} \\ \text{CSED} &= 5.3 \text{ otherwise} \end{aligned} \quad (163)$$

where OX is the oxide thickness in micrometer and CSED is expressed in MPa. The conversion of the oxide thickness in average fuel burnup depends on the material under consideration. Nevertheless, Bernaudat et al. concluded that the correlation derived for Zircaloy-4 could be (conservatively) applied to ZIRLOtm and M5tm.

Nevertheless, the strain energy density is not as easily measured in mechanical property tests as the plastic strain to failure, and direct measurements of this quantity are seldom made. In addition, the derivation of the SED from the (nonrepresentative) experiments relies on a constitutive relation for the material, and is also sensitive to the load and temperature history. There is thus no obvious benefit in using the critical SED instead of a critical strain in clad failure criteria for RIA (Jernkvist 2006).

In order to compare the rupture hoop strain or critical SED with the criteria currently adopted on the basis of the in-pile tests, they must be expressed in terms of maximum enthalpy (or enthalpy increase) in the fuel versus rod average burnup. The conversion requires the implementation in a fuel performance code such as the SCANAIR (Bernaudat and Pupier 2005; Jernkvist 2006) of FALCON code (Rashid et al. 2001), as well as fixing a fuel design and an irradiation history. At various burnup values, a RIA is then simulated by means of the fuel performance code in order to determine the peak enthalpy leading to the failure. Jernkvist (2006) compared the calculated clad failure thresholds for a hot zero power (HZP) rod ejection accident in a PWR obtained by means of the three above-mentioned codes, as shown in ► Fig. 40. The three computed curves differ not more than roughly 100 J/g, although the trends are slightly different because of differences in power histories and computer models such as failure criterion, clad corrosion, and the model for PCMI. However, the $\pm 1\sigma$ uncertainty band on the best-estimated clad failure threshold obtained by Jernkvist corresponds roughly to 120 J/g. The constant value around 700 J/g predicted by both FRAPTRAN and FALCON for burnup values below 40 MWd/kg are intended to preclude high-temperature clad failure in line with the current failure threshold.

Because of the above-mentioned limitations and scatter, Vitanza (2006) proposed an empirical model on the basis of the most representative integral tests. The limit is expressed directly in terms of the enthalpy as inferred from the experiments:

$$H_F = \left[200 \frac{25 + 10D}{bu} + 0.3\delta\tau \right] \left(1 - \frac{0.85\text{OX}}{W} \right)^2 - H_0 \quad (164)$$

■ Figure 40

Comparison of calculated clad failure thresholds for PWR hot zero power (HZP) rod ejection accident (Jernkvist 2006)

where H_F is the failure enthalpy in cal/g (if $H_F > 200$, set $H_F = 200$), bu is the burnup in MWd/kg (if $bu > 60$ set $bu = 60$), W is the cladding thickness, as-fabricated, in μm , $\delta\tau$ is the RIA pulse width (if $\delta\tau > 75$ ms, set $\delta\tau = 75$), ms. $H_0 = 0$ for the hot zero power (HZP) and $H_0 = 18(1-D)$ cal/g for the cold zero power (CZP) case. $D = 0$ (brittle) for spalled oxide and when $OX \geq 25\mu\text{m}$ for Zr-2 and Zr-4 and cold conditions and $OX \geq 45\mu\text{m}$ for advanced PWR cladding and cold conditions. $D = 1$ (ductile) for remaining conditions (Vitanza 2007). The term in the right-hand side that depends on the oxide thickness is similar to the function proposed by Chung et al. (1998). When comparing the values with those shown in ► Fig. 40 for low burnup fuel, it is evident that the fuel performance codes provide conservative estimations. Jernkvist attributed this to the penalizing choice of the accident scenarios: a Gaussian pulse shape and a low pulse width as well as an axial peak power chosen at the highest clad oxidation level.

As burnup progresses beyond 55–60 MWd/kg, the experimental data show no evidence of additional cladding strain enhancement (Bernaudat and Pupier 2005; Vitanza 2006; Vitanza and Conde Lopez 2005). This is why the burnup effect in Eq. (164) is limited up to 60 MWd/kg as shown in ► Fig. 41, which is in line with the burnup limit applied by Bernaudat and Pupier (2005). ► Figure 41 shows the predicted failure enthalpy versus burnup obtained for two PWR cases with respectively high and low corrosion. As one can observe, corrosion has a much more pronounced effect for a CZP than for a HZP RIA. This is because corroded cladding is brittle at low temperature (as low as room temperature), whereas it can retain ductility under hot conditions (unless oxide spalling prevails).

The effect of the cladding oxidation is also revealed in ► Fig. 42, which successfully compares the measured and the calculated failure enthalpy for the NSRR PWR tests that resulted in fuel failure. It should be pointed out, that while Eq. (164), predicts a significant impact of corrosion for CZP conditions, the corrosion effect under hot conditions is predicted to be much less pronounced (for non-spalled cladding). Furthermore, Eq. (164) also reflects the observation that corrosion and burnup act in synergy with each other, in that the burnup

■ Figure 41

Calculated failure enthalpy vs. burnup for two PWR instances, respectively with high and low corrosion, the latter for advanced cladding (left) and the corresponding corrosion buildup for the two instances (right). The predicted corrosion effect is very large for CZP conditions and moderate for hzp (with non-spalled fuel cladding)

■ Figure 42

Calculated and measured failure enthalpy vs. oxide thickness for NSRR PWR tests with PWR fuel

effects become stronger when corrosion is high and corrosion effects become more important when the burnup is high. Thus, expressing the RIA failure limit only in terms of burnup or only in terms of corrosion oxide thickness represents, according to this model, an oversimplification.

The experimental threshold versus burnup for all NSRR and CABRI MOX fuel are plotted in ► Fig. 43 and compared with the prediction on the basis of (164). The predictions follow the data very closely. The figure also shows that the failures of MOX fuel can be well predicted by the same failure threshold correlation used for UO_2 fuel, leading to the conclusion that a different treatment of MOX as compared with UO_2 fuel is not needed, at least for what failure threshold is concerned. This, however, does not exclude that other aspects could differ, for instance in relation to the post-failure behavior of the two types of fuel (Koo et al. 1997; Sasajima et al.

■ Figure 43

Calculated failure enthalpy and measured enthalpy for the MOX fuel tests performed in nsrr and CABRI

■ Figure 44

Calculated failure enthalpy on the basis of (164) versus measured fuel enthalpy

2000). More data are therefore required for the MOX behavior under RIA conditions before drawing definite conclusions. The same holds for Gd-doped UO_2 , for which data are scarce. Jernkvist (2006) mentioned tests in the NSRR on fresh fuel rods with Gd_2O_3 additions, where the observed failure threshold and failure behavior were not notably different from those of fresh UO_2 .

When comparing the failure enthalpy predictions of Vitanza with the experimental data in Fig. 44 it can be concluded that the predictions are satisfactory in that 85% of the non-failure data are below the median line and 85% of failures cases are along or above the median line. In addition to the median best-estimate prediction, Vitanza therefore proposed an empirical failure probability defined as a function of the distance from the best-estimate threshold, that

■ Figure 45

Probability distribution as function of distance from the best-estimate failure threshold, inferred from the prediction distribution shown in the previous figure and calculated with (165). The calculated points are obtained with two different weight factors for failure data. The solid line represents a rendition of the calculated probabilities. The diagram on the upper right side is the probability density obtained by deriving the probability function shown in the main figure

is, for and line parallel to the median line and distant from it by a certain amount δH_F :

$$P = 100N_{F\leq}/[N_{F\leq} + N_{>}] \quad (165)$$

where $N_{F\leq}$ is the number of failure data points that are below or along a given parallel line drawn at a certain distance from the median line of Fig. 44, and $N_{>}$ is the total number of data points (failed and non-failed) that are above such a line. By definition, the zero probability corresponds to the lowest failed data point, while 100% probability corresponds to the uppermost data point, as indicated by the dotted lines in Fig. 44. By applying (165) to the data in Fig. 44, the failure probability has been calculated as a function of distance from the best-estimate failure threshold. The result is shown in Fig. 45.

The same approach could be extended with weighting factors for the non-failure and failure data, or applied with a different best-estimate model when more data become available. The increasing amount of data is likely to reduce the uncertainty, but it should be underlined that the calculated thresholds for clad failure as well as for incipient melting are well above the enthalpy levels anticipated in high burnup fuel. Three-dimensional core kinetics analyses generally show that the peak radial average enthalpy is below 418 J/g (100 cal/g) in high burnup fuel.

7 Uncertainty Analysis

In general, uncertainties to be considered in fuel performance analysis may be grouped into three categories. The first category deals with prescribed quantities. The fuel rod performance code requires as input the fuel fabrication parameters (e.g., rod geometry, composition) and irradiation parameters (e.g., reactor type, coolant conditions, and irradiation history). The second category of uncertainties is the material properties, such as the fuel thermal conductivity or the fission gas diffusion coefficients. The third and last category of uncertainties is the so-called model uncertainties. A good example of such an uncertainty is the plain strain assumption in the axial direction (intuitively, it is clear that for a detailed analysis of pellet-cladding interaction, two- or three-dimensional models are indispensable). In order to assess the technological effect of all sources of uncertainties there are various techniques that may be considered.

First of all, there are various so-called sensitivity methodologies, ranging from multiple runs with input data or model parameters being varied, up to a rigorous mathematical treatment based on perturbation theory. Apart from the numerical noise technique, which is included in the TRANSURANUS code for example, perturbation theory has never been applied to fuel rod modeling, probably because the mathematical effort would be too great to formulate all the nonlinear phenomena in the form of basic differential equations. The numerical noise analysis allows the estimation of the standard deviation for instance of the center line temperature within just one run. For this purpose, the most important parameters of the fuel rod (e.g., q' and λ) are varied slightly on a random basis in an interval, which is similar to introducing numerical noise. These changes of model parameters result in modifications of the resulting quantities, which enables the analysis of the sensitivity of the code with respect to its parameters. The computational effort is therefore identical with that of a deterministic run, but there is no information available about the effect between various uncertain parameters. Furthermore, changes of parameters may only produce modifications in the results that are smaller than the numerical accuracy. This can be overcome with an increased accuracy through a compiler option, along with an appropriate adaptation of the convergence limits.

A second category of probabilistic approaches is the response surface technique. This is based on a careful combination of parameters called the experimental design, such as the Latin hypercube sampling or the Taguchi design. Peck (1980) tried this with the FRAP code. The main problem is that one has to decide in advance which parameter should be selected and how fine the variation of each parameter should be.

Finally, the Monte Carlo method is based on random sampling of all variables that are considered. It seems most attractive in view of its simplicity, but it entails high computational costs (increase by a factor 100–500), the knowledge about the distributions of the variables is rather limited, and it is unclear how much each parameter uncertainty contributes to the variation of the outcome. In order to reduce the computational costs, quasi-Monte Carlo methods may be applied. Instead of random sampling, quasi-random sampling sequences are recommended, which fill the space more uniformly than uncorrelated random numbers. They may be considered as a combination of the variations of parameters in response surface techniques with its experimental design and the standard Monte Carlo technique.

Despite the restrictions, applying a limited variation of some fabrication variable parameters in fuel rod performance calculations is being considered in several countries for two reasons. First of all, it is argued (Heins et al. 1991) that probabilistic calculations can replace a deterministic calculation with superimposed unfavorable tolerance limits on some fabrication

parameters (worst-case data set) in fuel design calculations. The results obtained with the deterministic worst-case calculation are said to be very conservative, with a degree of conservatism that would be difficult to quantify. Probabilistic calculations based on distributions on the other hand would allow the replacement of the worst-case data set by a data set leading to results with a known, defined conservatism. The industry, of course, would like to reduce the margins in this way. Secondly, it has been observed that in some cases the deterministic conservative approach did in fact not predict the worst fuel performance as in a probabilistic approach. This of course, depends on the proper definition of the worst case on one hand, and on the limits of variation of the variable parameters in the Monte Carlo approach on the other hand.

8 Outlook

In this chapter the main models have been outlined that are used for the simulation of the in-pile behavior of traditional pellet-in-clad nuclear oxide fuel and implemented in fuel performance codes. Most of these models contain semiempirical correlations that are valid within the confines of the parameters and irradiation conditions covered in the database used for their development and validation. Extrapolating the models beyond their range of validation is not appropriate, and would require extending the database with the corresponding experimental data, generally obtained from in-pile irradiations of real-scale fuel rods or elements. Because this approach of incremental design through experiments, their (semi)empirical interpretation or description, and validation is time consuming, expensive, and allows only limited progress, a more science-based approach is nowadays advocated. Although this so-called *multi-scale* approach is mainly addressing new fuel types (Stan 2009), the much larger amount of experimental data for conventional fuel enables the establishment and verification of this new approach and it can also help to strengthen the scientific basis for traditional oxide fuel.

Multi-scale here refers to the complex interrelationships of the processes taking place in irradiated material at the various scales of length and time, and the challenge is unraveling them to obtain a fundamental understanding of the basic underlying mechanisms. The multi-scale approach is hierarchical, based on passing information or parameters from the atomic scale up to structural length and time scales. A close coupling of experiments and computations is needed to achieve this goal. In particular the advances in computational sciences are a strong driving force since both software and hardware development allow nowadays reliable computations by means of quantum mechanical and molecular dynamic techniques at the atomistic scale and by phase field simulation, dislocation dynamics, or thermodynamics techniques at the mesoscale and continuum level. But also the advances in experimental sciences using spectroscopic techniques such as those offered by current generation synchrotron sources among others, also allow probing materials at atomistic scale, and eventually in situ.

The need for traditional fuel performance codes will, however, remain, particularly for calculating integral effects at the scale of the fuel rod, fuel element, or reactor core. Of course advances can be expected by integrating improved correlations and models resulting from the multi-scale approach into the codes. Relevant advances can also be expected from the transition from one-dimensional/two-dimensional to three-dimensional modeling using finite element solvers, as has been demonstrated for modeling of pellet-cladding interaction (Michel et al. 2010). Significant improvement in the analysis of reactor fuel rod behavior can therefore be expected in the coming decade.

Acknowledgment

The authors wish to thank D. Staicu (Institute for Transuranium Elements) for fruitful discussions, W. Goll (AREVA NP) and Nathalie Dupin (Calcul Thermo) for providing some of the figures and J. van der Laar for help for the preparation of some of the figures.

Abstract: This chapter deals with neutron fluctuations in nuclear systems. Such neutron fluctuations, or neutron noise, fall into two categories: neutron noise in zero power systems and neutron noise in power reactors. The concepts, the theory, and the methodology of these fluctuations as well as their various applications for extracting information in a nonintrusive way about the system in question are described. A number of specific applications are described, where detection and analysis of zero power and power reactor noise make it possible to extract diagnostic information about the system by determining some parameters of the system during normal operation, or by detecting, identifying, and quantifying developing anomalies at an early stage and determining their severity. This chapter ends with an outline of future developments and actual issues in the field.

1 Introduction

This chapter deals with the methods and techniques used in reactor surveillance and diagnostics, which are based on the analysis of fluctuations in the neutron population in a reactor core. These fluctuations appear as random variations of the detector counts at low power, or as fluctuations of the detector current at high power, representing two classes of neutron fluctuations, respectively. These two classes of neutron fluctuations, termed as zero power noise and power reactor noise, respectively, differ in their physical origin, hence their field of utilization, as well as have different mathematical description, and as the name indicates, they dominate at two different extremes of the magnitude of the neutron population in the core.

In low-power systems, the core material is constant in time. In such systems, the nontrivial (over-Poisson) distribution of the neutron population is brought about by the fact of branching, that is, the generation of several neutrons concurrently in the fission process. The fission process generates fission chains, and the neutrons in the same chain are time-correlated. Their joint detection has a non-Poisson distribution, and the deviation from the Poisson distribution can be used for different purposes. The theory of zero power noise is based on probability balance equations (master equations). The major applications are the measurement of the subcritical reactivity of a core, and the detection and quantification of fissile nuclear material in nuclear safeguards.

In power reactors, the effect of branching on the statistics of the neutron population is suppressed by another dominating effect. In such systems, several technological processes (boiling of the coolant/moderator in a BWR, vibrations of mechanical constructions in a PWR, etc., commonly called “noise sources”), cause the medium in which the neutron transport and multiplication takes place to fluctuate in time and space. These fluctuations again have a non-Poisson character, although not because of branching, rather because several neutrons in the system are affected simultaneously in the core in a *random* manner, and hence their parameters become correlated. A deterministic variation of the reactor material does not induce such correlations. The primary use of the information content of the neutron fluctuations so induced is to detect, identify, and quantify the noise sources. Both operational parameters in the normal state as well as changes of the reactor state to the abnormal state can be quantified as well as the occurrence of new anomalies can be detected and quantified. The methodology used to describe these stochastic processes is based on the linearized form of the Langevin technique.

In the following subsections, these phenomena and corresponding methods and applications will be described. This chapter starts with the theory and methodology of neutron noise in low-power systems. Applications for determining subcritical reactivity by various

fluctuation-based methods are described. Two newer areas of application, calculation, and use of zero power noise methods in accelerator-driven systems (ADSs) and in nuclear safeguards are then described. Thereafter, the concept of power reactor noise and the basics of the calculation of the dynamical response of a reactor to external perturbations are developed. The kinetic approximations in the theory of neutron noise and the different spatial components are defined and discussed. Expressions are given in one- and two-group diffusion theory for the Green's function, and the dynamic adjoint and the noise induced by some basic types of perturbations are calculated. The final two sections concern the application of neutron noise diagnostics for detecting and quantifying various anomalies as well as for determining some global core parameters of safety interest in BWRs and PWRs. This chapter concludes by giving an outlook on future trends of noise techniques.

2 Zero Power Reactor Noise

Historically, neutron fluctuations in a chain reaction were first studied in connection with “start-up with a weak source” (Harris 1964). In a multiplying system, including supercritical ones, when starting up the chain reaction with an external source, at the onset, the total number of neutrons is small; hence the relative fluctuations in the process are large. Thus, the time it takes before the avalanche of the supercritical behavior is established, and thus before the behavior of the system has a deterministic character, can vary from case to case significantly. This posed the question: what is the probability that, due to fluctuations in the neutron chain, criticality or prompt criticality could be attained in a system during start-up without an experimental indication. Another aspect of the start-up procedure, known from the much earlier studies of Watson and Galton (1873), is that the probability of the extinction of a supercritical branching process is larger than zero. This aspect has a bearing on the mechanism and success of detonating a nuclear device. Early work on this subject, constituting the real beginnings of these studies, is classified still as of this writing.

As is self-evident, all the above refers to the random aspects of transient behavior. However, the main use of zero power noise methods is found in utilizing the fluctuations in stationary low-power systems, such as a subcritical core with an extraneous source to measure the subcritical reactivity. A power reactor core during start-up and stepwise approaching criticality is an example. A low-power ADS that runs in subcritical state driven by an accelerator-based source is another example. In the following subsections, the principles and the main types of noise-based reactivity measurement methods are described. We also refer to the existing monographs and review articles, such as Thie (1963), Harris (1964), Uhrig (1966, 1970), Stacey (1969), Pacilio (1970), Williams (1974), Saito (1979), and the recent monograph by Pázsit and Pál (2008).

2.1 Methodology of Zero Power Neutron Noise

Zero power noise is concerned with the determination of the statistics of the neutron population in a multiplying system, and the statistics of detector counts during a time period or within two time gates a certain time apart. The emphasis is on the temporal evolution of the distributions, of which usually only that of the few lowest-order moments are determined explicitly. In the conventional description, space and energy effects are neglected, and only an integral parameter, the effective multiplication constant or the reactivity of the system, is sought. The description

assumes an infinite homogeneous system, into which an infinite homogeneous source and a detector are embedded. The approximation is often referred to as the “point reactor model.”

The theory of neutron fluctuations can of course be formulated in a general setting with space-energy-angular dependence included in a finite material, as it was already done in the first rigorous descriptions of the theory (Pál 1958, Bell 1965). However, the general treatment has the pragmatic drawback that the moment equations cannot be solved in a closed form, and the conceptual drawback that in a concrete case of applying the theory to reactivity measurement, the material and geometrical composition of the system is not known exactly (e.g., due to deviations from the assumed core composition by erroneous loading). If the composition of the system was known in all detail, the reactivity of the system could be determined purely by calculation. Space-energy corrections of the point model results can still be feasible and serve a better result than pure calculations when the composition of the system is only known approximately, such that this approximate knowledge can be used to improve the result of the measurement evaluated by the results of the space-independent theory. A crucial step in the correction methods is that the errors incurred by the imprecise knowledge of the system composition should only have a second-order small effect on the accuracy of the correction. The efficiency and accuracy of such correction methods is a subtle question whose discussion is beyond the scope of this chapter.

The methodology is based on probability balance equations, also called Kolmogorov or Chapman–Kolmogorov equations, and more recently just master equations. To calculate the transition probabilities of the system, one needs to define lumped parameters for the intensities of the various neutron processes and reactions. Hence, λ_c , λ_d and λ_f will denote the intensities of capture, fission, and detection of/by one neutron, respectively (these are often referred to in the literature as “transition probabilities per unit time”). These are, in turn, given as $\lambda_c = v\Sigma_c$, etc., where Σ_c is the macroscopic cross section of capture and v the neutron speed. Further, λ is the intensity (decay constant) of the decay of the delayed neutron precursors. The generation of neutrons and delayed neutron precursors is characterized by the probability $p_f(n, m)$ of emitting n neutrons and m delayed neutron precursors in a fission event. The distribution $p_f(n, m)$ has the property

$$\sum_{n,m} p_f(n, m) = 1$$

The above description corresponds to the simplified assumption of having one single averaged delayed neutron group. Using six delayed neutron groups instead of one is completely straightforward, and final results will be given also for six delayed neutron groups; however, such a more general treatment would spoil the transparency of the illustration here. Readers interested in the details of calculations with six delayed neutron groups are referred to the literature, for example, Pál (1958), Williams (1974), Kuang and Pázsit (1999), and Pázsit and Pál (2008).

Similarly to traditional (deterministic) transport theory, the problem can be formulated by two equivalent ways, namely through either forward (direct) or backward (adjoint) type master equations, respectively. The difference in the structure of the forward and backward equations is larger in the stochastic treatment than in the deterministic one, or one can say that the differences between the forward and backward equations increase with the moment order. Generally, for calculating higher moments, the backward approach is considered more effective and rigorous than the forward one. For illustration purposes, which is our goal here, the forward approach is more suitable; hence it will be used here to demonstrate the principles of the master equations for neutron fluctuations. In general, however, the backward approach is more

effective, and the majority of the publications is based on the backward equation, including the seminal work by Pál (1958) and in general when space and energy dependence is involved (Bell 1965; Munoz-Cobo et al. 1987). The very essence of the backward equations will also be shown, just to illustrate the differences between the two methods.

A typical quantity sought in neutron fluctuation problems is the probability

$$P(N, C, Z, t) \quad (1)$$

of having N neutrons and C delayed neutron precursors in the system at time t , and having detected Z neutrons in the time interval $[0, t]$, given that the process was started with zero neutrons and precursors in the system at $t = -\infty$, when an extraneous neutron source of intensity S was switched on. The reason for starting the process at $t = -\infty$ is that by $t = 0$, all transients will have decayed, and the neutron and precursor numbers can be assumed to be stationary processes. A more rigorous treatment would be to set the start of the neutron injection at a finite time t_0 and seek the probability of having N neutrons and C delayed neutron precursors at time t , and having detected Z neutrons in the time interval $[t - T, t]$, and then take the limit $t \rightarrow \infty$.

2.1.1 Forward Approach

The master equation is derived by constructing the probability $P(N, C, Z, t + dt)$ from that of $P(N, C, Z, t)$ by accounting for all possible transitions during dt . Assuming the mutually exclusive character of the events source emission, capture, detection, fission, and decay of a precursor within an infinitesimal time interval dt , and accounting for all possible transitions from the accessible states at time t to the state $\{N, C, Z\}$ at time $t + dt$, and by using the theorem of total probability and rearranging, the following master equation can be derived for $P(N, C, Z, t)$:

$$\begin{aligned} \frac{dP(N, C, Z, t)}{dt} = & \lambda_c P(N+1, C, Z, t)(N+1) + \lambda_d P(N+1, C, Z-1, t)(N+1) \\ & + \lambda_f \sum_n \sum_m P(N+1-n, C-m, Z, t)(N+1-n)p_f(n, m) \\ & + SP(N-1, C, Z, t) + \lambda P(N-1, C+1, Z, t)(C+1) \\ & - P(N, C, Z, t)[N(\lambda_f + \lambda_c + \lambda_d) + \lambda C + S]. \end{aligned} \quad (2)$$

The terms on the right-hand side can all be easily interpreted by accounting for the fact that the intensities of reactions refer to a single neutron, hence the multipliers N , $(N+1)$, etc. in the corresponding expressions. Note that here it is assumed that the detector is embedded in the multiplying medium, and capture in the detector competes with the other processes. Usually, the detector efficiency ε is introduced, defined as $\varepsilon = \lambda_d/\lambda_f$, which gives the ratio of the intensities of capture in the detector to the intensity of fissions in the system. A large detector efficiency in such a case means the introduction of a strong “parasitic” absorber, which hence modifies the reactivity of the original system. If the detector is placed outside the system, which is the case with the safeguards measurements treated later, a different formulation is necessary, where the escape of the neutrons from the system must be incorporated into the formalism. In such a case, just as in reality, the detector efficiency does not influence the progress of the chain reaction in the medium.

Since in a stationary system, the effect of the initial state has already decayed by $t = 0$, no initial condition needs to be specified for N and C . However, since the measurement starts at $t = 0$, one has the initial condition of $Z = 0$ at $t = 0$.

The solution of (2) cannot be given in a compact analytical form. However, one only needs the few lowest-order moments, which can be calculated in a straightforward manner, even if at the expense of some extensive algebra. In order to derive equations for the moments, it is practical and customary to introduce the generating functions of the probability distributions occurring in the equation. The generating functions are defined as

$$G(x, y, v, t) = \sum_N \sum_C \sum_Z x^N y^C v^Z P(N, C, Z, t) \quad (3)$$

and

$$g_f(x, y) = \sum_n \sum_m x^n y^m p_f(n, m) \quad (4)$$

The factorial moments of the random variables N , C , and Z are obtained as derivatives of G taken at its variables equal to unity, that is,

$$\langle N(t) \rangle \equiv N(t) = \left. \frac{\partial G(x, y, v, t)}{\partial x} \right|_{x=y=v=1} \quad (5)$$

and

$$\langle N(t)(N(t) - 1) \rangle = \left. \frac{\partial^2 G(x, y, v, t)}{\partial x^2} \right|_{x=y=v=1} \quad (6)$$

etc. The moments of the generating function

$$p(n, m) \quad (7)$$

are neutron physics constants, and the following notations will be used:

$$\left. \frac{\partial g_f(x, y)}{\partial x} \right|_{x=y=1} = \sum_n \sum_m n p_f(n, m) \equiv \langle v_p \rangle \equiv \langle v \rangle (1 - \beta) \quad (8)$$

and

$$\left. \frac{\partial g_f(x, y)}{\partial y} \right|_{x=y=1} = \sum_n \sum_m m p_f(n, m) \equiv \langle v_d \rangle \equiv \langle v \rangle \beta \quad (9)$$

where $\langle v \rangle = \langle v_p \rangle + \langle v_d \rangle$ is the expectation of the total (prompt plus delayed) neutron number per fission, and the delayed neutron fraction β was also introduced.

Using the above definitions, (2) is converted into

$$\begin{aligned} \frac{\partial G(x, y, v, t)}{\partial t} = & \{ \lambda_f [g_f(x, y) - x] - \lambda_c(x - 1) - \lambda_d(x - v) \} \frac{\partial G(x, y, v, t)}{\partial x} \\ & + \lambda(x - y) \frac{\partial G(x, y, v, t)}{\partial y} + (x - 1)SG(x, y, v, t) \end{aligned} \quad (10)$$

This is the typical form of the forward master equation for branching processes. It is a linear partial differential equation. The various equations for the moments are then obtained by taking the derivatives of G with respect to the auxiliary variables x , y , and u , leading to a system of coupled ordinary differential equations.

Before giving an illustration of the technique, at this point, it is worth to make a small diversion. Assume that the neutrons are injected into a medium not containing fissile material, that is, $\lambda_f = 0$; hence delayed neutrons do not occur either, and we are not concerned with the number of detections (one takes $\nu = 1$), rather we only study the statistics of the neutron number. Then, (10) is converted to

$$\frac{\partial G(x, t)}{\partial t} = \lambda_a(1 - x) \frac{\partial G(x, t)}{\partial x} + (x - 1)S(t)G(x, t) \quad (11)$$

where $\lambda_a = \lambda_c + \lambda_d$. In the above, a time-dependent source is allowed for, to indicate the generality of the statement for non-multiplying systems. From (11), it follows for the expectations that

$$\frac{d \langle N(t) \rangle}{dt} = -\lambda_a \langle N(t) \rangle + S(t) \quad (12)$$

Here, and only here, to avoid confusion, we kept the notation on the expectation value for the first moment. With this, it is seen that the full solution of (11) is obtained as

$$G(x, t) = e^{(x-1)\langle N(t) \rangle} \quad (13)$$

since substituting (13) into (11) will lead to (12). Equation (13) is, on the other hand, the generating function of the Poisson distribution

$$P(N, t) = \frac{e^{-\langle N(t) \rangle} \langle N(t) \rangle^N}{N!} \quad (14)$$

It is thus seen that the number of particles in a non-multiplying medium (i.e., one in which branching does not occur) follows Poisson statistics even with a (deterministically) time-varying source intensity. (If the source intensity is a random process, as in some of the cases of pulsed ADS experiments described in the forthcoming sections, the statement is not true). It will be seen soon that branching, that is, the presence of fission, will bring about deviation from the Poisson statistics.

Turning back to (10), we illustrate its use for deriving the first moments; obtaining the higher moments goes in a similar way. Taking the derivatives with respect to x , y , and ν at $x = y = \nu = 1$ yields the coupled equation system

$$\frac{dN(t)}{dt} = \frac{\rho - \beta}{\Lambda} N(t) + \lambda C(t) + S \quad (15)$$

$$\frac{dC(t)}{dt} = \frac{\beta}{\Lambda} N(t) - \lambda C(t) \quad (16)$$

and

$$\frac{dZ(t)}{dt} = \lambda_d N(t) = \epsilon \lambda_f N(t), \quad t \geq 0. \quad (17)$$

Here the conventional notations

$$\rho = \frac{\langle v \rangle \lambda_f - (\lambda_f + \lambda_c + \lambda_d)}{\langle v \rangle \lambda_f} \quad (18)$$

and

$$\Lambda = \frac{1}{\langle v \rangle \lambda_f} \quad (19)$$

were introduced, where ρ is the reactivity and Λ is the prompt neutron generation time. Also, in these equations, a stationary source was assumed with a constant intensity. Equations (15) and (16) are recognized as the standard point-kinetic equations, as expected.

As is seen from the above, the forward master equation leads to a coupled system of ordinary differential equations for the moments, whereas as we shall see, in the backward approach, each moment can be calculated independently of the others.

Due to the stationary state of the system, the neutron and precursor numbers are constants; hence the time derivatives on the left-hand sides of (15) and (16) are zero. This yields a solution for the stationary neutron and precursor numbers as

$$N = \frac{\Lambda S}{-\rho} \quad (20)$$

and

$$C = \frac{\beta N}{\lambda \Lambda} = \frac{\beta S}{\lambda(-\rho)} \quad (21)$$

The solution of (17) with the initial condition $Z(0) = 0$ is obtained as

$$Z(t) = \varepsilon \lambda_f N t = \varepsilon \lambda_f \frac{\Lambda S}{-\rho} t \quad (22)$$

The derivation of higher moments goes in an analogous manner and is quite straightforward. It can be found in the literature, so the details will not be given here.

2.1.2 Backward Approach

Here only the principles will be given in a very cursory way. When using the backward equations with a source, it is necessary to progress in two steps. Since the backward equation operates on initial variables, the master equation that describes the evolution of the population concerns a cascade that was started by one initial neutron. In order to calculate the distributions of a cascade induced by a source of particles with an intensity S , one needs to use a second master equation, connecting the single-particle induced and source-induced distributions, or their generating functions. The probability distributions and corresponding generating functions and moments will be distinguished by using lower-case-letters for the single-particle induced processes, and upper-case-letters for the quantities corresponding to the extraneous source.

In the backward approach, the probability of finding the system in the state $\{N, C, Z\}$ at time t is calculated by following up the first reaction of the particle in $[t_0, t]$ (integral form of the backward equation) or within $[t_0, t_0 + dt_0]$ (differential form). However, due to time homogeneity in a stationary system, the distributions depend only on $t - t_0$, hence operation on t_0 can be transferred to operating on t . Thus, to simplify the notations, we will set $t_0 = 0$, and will derive a master equation by considering the possible events within $[0, dt]$. By this approach, we will arrive to the so-called “mixed” form of the master equations, in that the time variable (and only this variable) will refer to the terminal value and not the initial one. In all other respects, the equations will have the property of the backward approach. In fact, the mixed-type equations are often referred to as backward equations in the literature.

Hence we will seek the probability distribution

$$p(n, c, z, T, t) \quad (23)$$

that there will be n neutrons and c precursors in the system at time t , induced by one initial neutron at $t = 0$, and that there have been z detector counts registered between $t - T$ and t . The stationary state of the system is attained by considering the solution for $t \rightarrow \infty$. The source emission is taken into account by deriving another backward master equation to connect the single-particle induced distribution function $p(n, c, z, T, t)$ with the probability distribution $P(N, C, Z, T, t)$ of the source emission case, when the source was switched on at $t = 0$.

The construction of the differential backward equation connecting the two distributions is based on summing up the probabilities of the mutually exclusive events of not having or having a source emission event in dt , respectively:

$$\begin{aligned} P(N, C, Z, T, t) = & (1 - Sdt)P(N, C, Z, T, t - dt) \\ & + Sdt \sum_{\substack{N_1 + n_2 = N \\ C_1 + c_2 = C \\ Z_1 + z_2 = Z}} P(N_1, C_1, Z_1, T, t) p(n_2, c_2, z_2, T, t) \end{aligned} \quad (24)$$

Here the last product term on the right-hand side expresses the fact that the initial particle injected at $t = 0$ and the source particle injected within dt at t lead to independent chains of neutrons and precursors as well as detector counts, and one has add up to all possible combinations of the mutually exclusive events of the source neutron leading to N_1 neutrons while the initial particle leads to $N - N_1 = n_1$ neutrons at time t etc.

The summation in the last term of (24) is of the form of a discrete convolution, which, in analogy with the continuous Laplace transform, will be converted to a simple product of the generating functions of the corresponding probabilities. Introducing the generating functions $G(x, y, v, T, t)$ and $g(x, y, v, T, t)$ of $P(N, C, Z, T, t)$ and $p(n, c, z, T, t)$, respectively, one arrives from (24) at

$$\frac{dG(x, y, v, T, t)}{dt} = SG(x, y, v, T, t) \{g(x, y, v, T, t) - 1\} \quad (25)$$

In this equation, the variables x , y , and v are only parameters, on which no operations are made. Hence, once an equation for $g(x, y, v, T, t)$ or its moments are obtained, the corresponding moments of $G(x, y, v, T, t)$ can be determined independently from the other moments. This

is a definite difference between the two approaches: the forward approach leads to a coupled system of differential equations of increasing order for the higher moments; in the backward approach, the higher moments of a random variable can be determined by performing nested integrals of increasing order of nesting for the moments of increasing order. Besides, it turns out that the single-particle induced first moment of the neutron number is the kernel (or Green's function) of all higher-order moments. Thus, once this simple expectation $n(t)$ is determined, there are no more equations to solve, only integrals to be performed. This feature of the backward equation makes it more straightforward than the forward approach, although technically, calculating the integrals is not necessarily simpler than solving the coupled system of ordinary differential equations.

By accounting for the initial conditions

$$g(x, y, \nu, T, 0) = x \quad \text{and} \quad G(x, y, \nu, T, 0) = 1, \quad (26)$$

equations (25) can be easily integrated to obtain the solution

$$G(x, y, \nu, T, t) = \exp \left\{ S \int_0^t [g(x, y, \nu, T, t') - 1] dt' \right\}. \quad (27)$$

The stationary value of this distribution, from which the moments can be calculated, is given by

$$G(x, y, \nu, T) = \lim_{t \rightarrow \infty} G(x, y, \nu, T, t) = \exp \left\{ S \int_0^\infty [g(x, y, \nu, T, t') - 1] dt' \right\} \quad (28)$$

The moments of $G(x, y, \nu, T)$ can be obtained by taking the derivatives, which will lead to expressions supplying the moments in terms of integrals of corresponding moments of $g(x, y, \nu, T)$.

The calculation of the single-particle induced moments goes as follows. In addition to the already defined probability $p(n, c, z, T, t)$, one needs also to define

$$w(n, c, z, T, t)$$

as the probability that there are n neutrons and c precursors at time t in the system, induced by one initial precursor at $t = 0$, and that there have been z detector counts between $t - T$ and t . The corresponding probability generating function, defined in the usual way, will be denoted as $h(x, y, \nu, T, t)$.

The master equations for g and h can be obtained as follows. With the usual arguments one writes

$$\begin{aligned} p(n, c, z, T, t) = & (1 - \lambda_a dt) p(n, c, z, T, t - dt) + \lambda_c \delta_{n,0} \delta_{c,0} \delta_{z,0} dt \\ & + \lambda_f dt \sum_{k,\ell} p_f(k, \ell) \sum_{\substack{n_1+n_2=n \\ c_1+c_2=c \\ z_1+z_2=z}} A_k(n_1, c_1, z_1, T, t) B_\ell(n_2, c_2, z_2, T, t) \quad (29) \\ & + \lambda_d dt \delta_{n,0} \delta_{c,0} [\Delta(t, T) \delta_{z,1} + \bar{\Delta}(t, T) \delta_{z,0}], \end{aligned}$$

where

$$A_k(n_1, c_1, z_1, T, t) = \sum_{\substack{n_{11} + \dots + n_{1k} = n_1 \\ c_{11} + \dots + c_{1k} = c_1 \\ z_{11} + \dots + z_{1k} = z_1}} \prod_{j=1}^k p(n_{1j}, c_{1j}, z_{1j}, T, t), \quad (30)$$

and

$$B_\ell(n_2, c_2, z_2, T, t) = \sum_{\substack{n_{21} + \dots + n_{2k} = n_2 \\ c_{21} + \dots + c_{2k} = c_2 \\ z_{21} + \dots + z_{2k} = z_2}} \prod_{j=1}^\ell w(n_{2j}, c_{2j}, z_{2j}, T, t). \quad (31)$$

The function $\Delta(t, T)$ is defined as

$$\Delta(t, T) = \begin{cases} 1 & \text{for } 0 \leq t \leq T, \\ 0 & \text{otherwise} \end{cases} \quad (32)$$

and $\bar{\Delta}(t, T) = 1 - \Delta(t, T)$.

With similar arguments, for the precursor-induced cascade one obtains

$$w(n, c, z, T, t) = (1 - \lambda dt)w(n, c, z, T, t - dt) + \lambda dt p(n, c, z, T, t). \quad (33)$$

Turning to the generating functions, eliminating the generating function $h(x, y, \nu, T, t)$ of the precursor-initiated distributions by solving the equation obtained from (33), one arrives to an equation containing only the generating function $g(x, y, \nu, T)$ that is to be used in (28) to calculate the moments of the source-induced distributions. The equation reads as

$$\begin{aligned} \frac{\partial g(x, y, \nu, T, t)}{\partial t} = & \lambda_f \sum_k \sum_\ell p_f(k, \ell) [g(x, y, \nu, T, t)]^k \left[\lambda \int_0^t e^{-\lambda(t-t')} g(x, y, \nu, T, t') dt' \right. \\ & \left. + y e^{-\lambda t} \right]^\ell + \lambda_c - \lambda_a g(x, y, \nu, T, t) + \lambda_d \{(\nu - 1)\Delta(t, T) + 1\}. \end{aligned} \quad (34)$$

Here one can note a significant difference compared to the forward equation. As (34) shows, in the backward formalism, one gets one single equation for the generating function g . Since the equation does not contain any derivatives with respect to the variables x , y , or ν , one single equation can be derived for any individual moment of any order, which can be solved separately from the other moment equations. This property holds also for (28) which is used for the calculation of the moments of the source-induced distributions from those of the single-particle induced ones. The only technical difficulty of the solution is the calculation of nested integrals of increasing order with increasing moment order. In the forward formalism, there is also one single master equation as a starting point. However, the equation contains derivatives with respect to x and y (see (10)). Because of this, for any moment except the first moment of the detector count, a coupled system of differential equations arises. The order of the system is increasing with the order of the moments. This, in general, constitutes more difficulties in the solution than the performing of the multiple integrals in the backward case.

2.2 Reactivity Measurements in Traditional Systems with Stationary Poisson Sources

The typical situation of measuring reactivity in a subcritical system is shown in ► Fig. 1. One approaches criticality gradually either by adding more fuel to the core, or lifting out a control rod. At each step, the level of criticality is determined, in order to know the margins to criticality. It is obvious that one single static measurement of the detector counts and using (22) is not practical, since in order to determine ρ , one has to know both the detector efficiency and the source strength in absolute terms. Besides, equation (22) was derived in the infinite homogeneous reactor approximation in which the detector efficiency is defined as the ratio of the fission cross sections, but in reality, it will include also geometrical factors due to the finite size of the detector. Hence, this efficiency can also change when new fuel is added to the core. In a more formal way of expressing it, the source S , the detector efficiency ε , and the prompt neutron generation time Λ in (22) can be expressed as adjoint-weighted integrals of the underlying space- and energy-dependent quantities (source spectrum, detector, and fission cross sections) (Ott and Neuhold 1985), and the weighting adjoint changes with the system configuration. In either case, this means that both ε and S are unknowns, and they need to be considered as dependent on the core configuration. Since the detector count depends linearly on the measurement time gate, comparing measurements of different lengths does not help either.

Therefore, in all cases the reactivity is determined from ratios of measurements of some kind, such as in two different configurations in the system or using time-dependent measurements and using detector counts at different times. The use of ratios of detector counts plays two different roles. Partly, in principle it can eliminate the unknown parameters from the corresponding expressions, which is the main goal. Partly, in a fortunate case, the inaccuracy of the method, caused by the deviations between the point model in which the formulas were derived and the real practical case, might be decreased by taking ratios if both quantities are biased toward the same direction.

However, taking the ratios may also introduce new problems. Consider for instance the most straightforward case of performing two static measurements, one in a state with a known

■ Figure 1
Illustration of the reactivity measurement method

reactivity ρ_1 , and one with an unknown reactivity ρ_2 . Using (22) one has

$$Z_1(t) = \varepsilon \lambda_f \frac{\Lambda S}{|\rho_1|} t; \quad Z_2(t) = \varepsilon \lambda_f \frac{\Lambda S}{|\rho_2|} t; \quad \rho_2 = \rho_1 \frac{Z_1(t)}{Z_2(t)} \quad (35)$$

The problem with this method is that, as indicated above, the parameters ε , Λ , and S are in general different in the two states, hence the last expression of (35) still contains ratios of unknown quantities.

One way of avoiding this difficulty is to perform time-dependent measurements, and extract the sought parameters from the time-dependence of the detector response in one single measurement. This is the essence of the pulsed neutron measurements. An analysis of (15) and (16) shows that the detector count rate, taken to be proportional to the temporary neutron level, decays in time with two different decay constants, given by the characteristic equation of (15) and (16), which is also the so-called inhour equation. With one delayed neutron group in a subcritical system, there are only two negative roots ω_0 and ω_1 , respectively. In practical work, one uses their positive values instead, and these are called the prompt and delayed neutron decay constant. In systems not too far from critical, they are given with a good approximation as

$$\alpha_p \equiv \alpha = -\omega_1 = \frac{\beta - \rho}{\Lambda} \quad (36)$$

and

$$\alpha_d = -\omega_0 = \frac{\lambda \rho}{\rho - \beta} \quad (37)$$

The experiment is performed by injecting a pulse in the system and analyzing the temporal decay of the detector count rate. After a transient period of pulse injection and a subsequent period during which the shape of the neutron distribution has to readjust to the fundamental mode, the temporal variation of the neutron population can be described asymptotically as

$$N(t) = N(0)e^{-\alpha t} = N(0) \exp \left\{ -\frac{\beta - \rho}{\Lambda} \right\} \quad (38)$$

From such a measurement, the prompt neutron decay constant α can be determined. An illustration of such a measurement is seen in  Fig. 2, taken from two different configurations of the MUSE experiments, performed by the MUSE collaboration (Mellier 2005).

The parameter α contains, in addition to the reactivity, also the effective delayed neutron fraction β and the prompt neutron generation time Λ , which are also unknown. It is often desirable to obtain either the reactivity ρ directly, or the reactivity in dollars ρ/β , and determine Λ in a separate measurement. One possibility would seem to be to perform a measurement at prompt critical to determine $\alpha_c = \beta/\Lambda$, and hence to determine the reactivity as

$$\frac{\rho}{\beta} = \frac{\alpha_c - \alpha}{\alpha_c} \quad (39)$$

However, this method suffers from the problem mentioned before, namely that the values of Λ and β differ in the critical and subcritical case.

■ Figure 2

Pulsed neutron experiments made on the fast research reactor core MASURCA in the MUSE project (The MUSE collaboration, Mellier 2005)

To avoid this problem, an ingenious method was devised by Sjöstrand (1956) usually referred to as the area ratio method. A simple analysis of (15) and (16) shows that taking the ratio of the area A_p of the prompt peak and the delayed area A_d , one has

$$\frac{A_p}{A_d} = \frac{-\rho}{\beta} \quad (40)$$

This is the celebrated Sjöstrand-formula or area ratio formula (Sjöstrand 1956). With this method the reactivity in dollars can be determined without the need of knowing either of Λ , ε , or S quantitatively. The key to this success was to use both a dynamic method *and* the ratio of two measured quantities, taken from the same system.

By using only one single pulse, practical application of the method would be hard, due to low neutron levels and interference from the background, making the determination of the delayed area impossible. Hence the method is used with periodic pulsing with a repetition period T such that $1/\alpha \ll T \ll 1/\alpha_d$. This way the prompt peak has sufficient time to die away between the pulses, whereas the delayed part does not decay significantly. After several hundred pulses, an approximately constant delayed background will be built up, whereas the prompt peak will be practically unchanged. It can be easily shown that calculating A_d as the delayed area within the period will leave (40) unchanged. This way the delayed area A_d can be determined with much bigger accuracy.

The area ratio method has been used with much success in reactivity measurements throughout the years. It has been proven to be very robust and working well in various systems, bare and reflected as well as in thermal and fast systems. Naturally, strong deviations from point kinetics make it work less accurately; thus several modifications of the original method were suggested, such as the extrapolated area ratio method, which under special circumstances can perform better. On the whole, however, the area ratio method is the most reliable pulsed neutron measurement method.

One reason for its success, seldom discussed and even more seldom investigated numerically, is the fact that it uses the ratio of two independent quantities from one and the same measurement. It is surmised that inaccuracies arising from the deviation from point kinetics cancel to a certain degree due to taking the ratio of the two independently measured parameters with the same detector. The Sjöstrand method shares this potential strength with the

fluctuation-based methods described below, which are also based on the ratio of two parameters measured in the same system, often with the same detector.

2.2.1 The Feynman-Alpha (Variance to Mean) Method

From the pragmatic point of view the pulsed neutron experiments described above have the drawback that they require access to a pulsed neutron generator. Radioactive neutron sources lend a much larger flexibility to perform measurements and they are much more readily available. They are not suitable to extract dynamic parameters the same way as the pulsed neutron experiments do, that is, utilizing only the time-dependence of the expectations, but this is where the noise measurements make their presence.

The essence of the noise measurements is that the correlations in the prompt chain between the neutron numbers or detector counts at different times in a subcritical reactor die out with the same prompt neutron decay constant as the one in the pulsed experiments. Although it sounds intuitively very plausible, this statement is far from trivial, and it had to be derived by rigorous methods for verification (Pál 1958). The methods described in the forthcoming sections determine the prompt neutron decay constant by only using a stationary neutron source. In addition, by using the first two moments of the neutron counts and using the dynamics in the evolution of the correlations, they also eliminate the unknown parameters S and ε . Eliminating Λ with using the properties of both the prompt and delayed decay modes is not as simple though as in the case of the pulsed experiments.

The principle of the Feynman-alpha method is to measure the detector counts during a measurement time duration (gate) t repeatedly and to calculate the variance to mean, that is, the relative variance, of the detector counts. Then, the measurement is repeated at different measurement times to obtain the time-dependence of the variance to mean. The time-dependence of the variance to mean will be determined by the prompt and delayed neutron decay constants.

The derivation of the variance to mean formula can be made via the forward approach by continuing the procedure of calculating the moments as outlined in [Sect. 2.1.1](#) Taking all possible second-order derivatives of (10), one obtains a coupled linear ordinary differential equation system with constant coefficients of order six for the six moments $\langle N(N-1) \rangle$, $\langle NC \rangle$, $\langle C(C-1) \rangle$, etc. Solution of this equation system is quite straightforward, and the relative variance of the detector counts as a function of the measurement time can be obtained. The result can be compactly written as

$$\frac{\sigma_Z^2(t)}{Z(t)} = 1 + \varepsilon \frac{\lambda_f^2}{(\alpha + \lambda)} \sum_{i=1}^2 \frac{W(\alpha_i)}{(\alpha_i - \alpha_j)} f_i(t); \quad i, j = p, d; \quad i \neq j \quad (41)$$

or, introducing the Feynman $Y(t)$ function as

$$Y(t) \equiv \frac{\sigma_Z^2(t)}{Z(t)} - 1, \quad (42)$$

alternatively one has

$$Y(t) = \varepsilon \sum_{i=1}^2 A_i f_i(t) = \varepsilon \left[A_1 \left(1 - \frac{1 - e^{-\alpha t}}{\alpha t} \right) + A_2 \left(1 - \frac{1 - e^{-\alpha_d t}}{\alpha_d t} \right) \right] \quad (43)$$

In (41) the following definitions were used:

$$W(s) \equiv \left(1 - \frac{\lambda^2}{s^2}\right) \langle v_p(v_p - 1) \rangle - \frac{\lambda^2}{s^2} 2\langle v_p \rangle \langle v_d \rangle \quad (44)$$

and

$$f_i(t) \equiv 1 - \frac{1 - e^{-\alpha_i t}}{\alpha_i t}; \quad i = p, d. \quad (45)$$

For six delayed neutrons, a completely analogous expression is valid, with the sum in (41) and (43) running from $i = 0$ to 6 (for the details see Pázsit and Pál 2008).

From (41) it is seen that the variance is over-Poisson in the case when branching is present. The sought parameter α is contained in the part of the relative variance exceeding unity. Similarly to the cases discussed earlier when ratios of various measured quantities are calculated, the source intensity S is not present in the formula. The detector efficiency ε does not disappear, but due to the nonlinear dependence of the relative variance on time, the parameters $\alpha = \alpha_p$ and α_d can be extracted by a fitting of the theoretical curve to the measurement without knowledge of the detector efficiency. An illustration of Feynman-Y functions with various reactivity values in units of 10^{-4} is shown in ► Fig. 3.

The approximate expressions for the factors A_1 and A_2 read, for not too deep subcriticalities as

$$A_1 = \frac{D_{v_p}}{(\beta - \rho)^2} \quad (46)$$

■ Figure 3

Feynman-Y values as functions of time, for various values of subcritical reactivity in units of 10^{-4}

and

$$A_2 = \frac{D_{v_p}}{(\rho - \beta)^2} \left[\left(\frac{\rho - \beta}{\rho} \right)^2 - 1 \right] = A_1 \left[\left(\frac{\rho - \beta}{\rho} \right)^2 - 1 \right] \quad (47)$$

where the prompt neutron Diven factor D_{v_p} was introduced, whose definition is

$$D_{v_p} = \frac{\langle v_p(v_p - 1) \rangle}{\langle v_p \rangle^2} \quad (48)$$

Since for $1/\alpha \ll t_1 \ll 1/\alpha_d$ one has

$$Y(t_1) = \varepsilon A_1 \quad (49)$$

and for $1/\alpha_d \ll t_2$

$$Y(t_2) = \varepsilon(A_1 + A_2), \quad (50)$$

in principle one has a similar possibility as with the Sjöstrand method, namely to determine ρ/β from $Y(t_1)/Y(t_2)$ without knowledge of Λ . However, unlike in the case of the former method where the pulse repetition could shorten the measurement time, with the Feynman-alpha method one needs long measurement times comparable with the delayed neutron time constants, which are not performed for practical cases. On the other hand, the advantages of determining the reactivity (or prompt neutron decay constant) from the ratio of two independent quantities from the same measurement (the first two moments of the neutron count) are still the same, namely that the method is relatively insensitive to deviations from the point-kinetic behavior.

The Feynman-alpha formula can be derived by accounting for six delayed neutron groups with fractions β_i decay constants λ_i , $i = 1 \dots 6$, with the same methods, at the expense of more complicated algebra. For the sake of completeness, the formula is given below. With one prompt and six delayed neutron groups, the time-dependence of the system will be characterized by the seven roots s_i of the characteristic equation, also called the “inhour equation”:

$$s \left(\Lambda + \sum_{i=1}^6 \frac{\beta_i}{s + \lambda_i} \right) - \rho = G^{-1}(s) = 0, \quad (51)$$

where $G(s)$ is the so-called zero power transfer function. With these preliminaries, the Feynman-alpha formula for six delayed neutron groups can now be given as

$$Y(t) = \frac{\mu_{ZZ}(t)}{Z(t)} = \sum_{i=0}^6 Y_i \left(1 - \frac{1 - e^{-\alpha_i t}}{\alpha_i t} \right), \quad (52)$$

where $\alpha_i = -s_i$, $i = 0, 1, \dots, 6$, and where t stands for the measurement time length. An explicit expression for the coefficients Y_i can be given by assuming that the probability of the simultaneous generation of two delayed neutron precursor nuclei, either in the same or in different groups, is zero or negligible, in the form

$$Y_i = 2\varepsilon D_v A_i \frac{G(\alpha_i)}{\alpha_i}, \quad (53)$$

where the A_i are the residues of G at s_i . Explicit expressions for the residues A_i can be found in Pázsit and Pál (2008) and a derivation for the most general case of all second-order precursor generating possibilities retained is given by Kuang and Pázsit (1999, 2002).

With the concrete values of the prompt neutron generation time Λ and the delayed neutron decay constants λ_i , even in a slow (thermal) reactor, the character of the solution given by (52) will be qualitatively very similar to the solution (43), calculated by assuming one average delayed neutron group. There will be a prompt part of the $Y(t)$ curve for short measurement times, and a delayed part for long times. In practical work, the prompt part is usually utilized.

Performing a Feynman-alpha measurement in practice means that one has to count the detector pulses during time intervals of length t repeatedly, in order to estimate the mean and the variance. The repetition is achieved by performing detection during a longer period and then dividing the total time length into sections of equal length and estimating the mean and the variance as arithmetic averages of the counts in these adjacent as well as nonadjacent intervals. Such an estimate will be biased as compared to the theoretical formula for two reasons. One reason is the finite number of samples used in the arithmetic averaging, and the other, more important circumstance is that the detector counts in time slots lying close to each other will not be independent random variables (the covariance is not zero). Theoretical expressions for the bias of the measurement, in terms of the sample population and the separation of the measurement intervals are given by Pázsit and Pál (2008).

Actually, the fact that the number of counts in adjacent or not too far separated intervals is not independent, can be used to construct measurement methods that utilize the information in the covariance of the count numbers in closely lying intervals. Such a method, the Bennett method, will be described below.

2.2.2 The Rossi-Alpha (Correlation) Method

The Rossi-alpha method is similar to the Feynman-alpha method. Instead of measuring the dependence of the relative variance of the detector counts in a time interval t , a covariance-type quantity is considered. Namely, the conditional probability of detecting a neutron in $(t + \tau, dt)$, given that a detection was made at t is considered. Since for an infinitesimal time dt the probability of a detection is equal to the expectation of the detections, this conditional probability can be written in terms of a covariance function. Based on the previous definitions, the Rossi-alpha formula is defined as

$$R(\tau)d\tau = \frac{\langle Z(t, dt)Z(t + \tau, d\tau) \rangle}{\langle Z(t, dt) \rangle} = \frac{C_{ZZ}(\tau)}{Z dt} + Z d\tau \quad (54)$$

where Z is the constant detection rate in the stationary system, and $C_{ZZ}(\tau)$ is the covariance function, defined as

$$C_{ZZ}(\tau) = \langle Z(t, dt)Z(t + \tau, d\tau) \rangle - \langle Z(t, dt) \rangle \langle Z(t + \tau, d\tau) \rangle \quad (55)$$

In a stationary system, the right-hand side obviously does not depend on t , only on the delay time τ . In the literature, the first term in the last equality of (54) is often referred to as the “correlated counts,” and the last term as the “uncorrelated background.” The information on the sought parameter α is contained in the covariance to the mean, that is, the first of these

two terms, through its dependence on τ . Thus, due to its simpler form and the fact that the information is contained in that term, we shall refer to the Rossi-alpha formula as the covariance to the mean, $P_r(\tau)d\tau$, that is,

$$P_r(\tau)d\tau = \frac{C_{ZZ}(\tau)}{Z dt}, \quad (56)$$

but in the literature the $R(\tau)$ of (54) is also referred to as the Rossi-alpha formula. The $P_r(\tau)$ above can be calculated from a two-point (in time) master equation in a way similar to the calculation of the Feynman-alpha formula. With the details we refer to Pázsit and Pál (2008). The final result can be written in a form similar to that of the Feynman-alpha:

$$P_r(\tau)d\tau = \varepsilon \frac{\lambda_f^2 d\tau}{2(\alpha + \lambda)} \sum_{i=1}^2 \frac{W(\alpha_i)}{(\alpha_i - \alpha_j)} f_i(t); \quad i, j = p, d; \quad i \neq j \quad (57)$$

where the functions $W(s)$ are identical with those in (44), but now the functions $f_i(t)$ are different from those of the Feynman-formula:

$$f_i(\tau) \equiv \alpha_i e^{-\alpha_i \tau}, \quad i = p, d. \quad (58)$$

Hence the Rossi-alpha formula can be written in the form

$$P_r(\tau)d\tau = \varepsilon(\alpha A_1 e^{-\alpha \tau} + \alpha_d A_2 e^{-\alpha_d \tau})d\tau \quad (59)$$

It is thus seen that the correlated part of the Rossi-alpha formula decays with the same decay constants as the detector count rate in the pulsed experiments. As is usual with the Feynman-alpha method, only the prompt part of the measurement is utilized, for the determination of the prompt neutron decay constant α . Similar to the Feynman-alpha method, space effects are suppressed by the ratio of the second-and first-order moments, although the domains of validity are not exactly the same for the two methods.

In a way analogous to the Feynman-alpha method, the Rossi-alpha formula can be calculated for six delayed neutron precursor groups with the result

$$P_r(\tau) = \frac{1}{2} \sum_{i=0}^6 Y_i \alpha_i e^{-\alpha_i \tau}, \quad (60)$$

where the coefficients Y_i are the same as in (53).

It may be interesting to note that an analogue of the fact that the second factorial moment of a discrete random variable in a volume of the phase space can be obtained from an integral of its two-point distribution (correlation function), exists to connect the Rossi- and Feynman-alpha expressions. Namely, once the Rossi-alpha formula for a process is known (or the two-point distribution of particle detection at two infinitesimal times), the Feynman-alpha formula, based on the variance of the detection number over a finite time period, can be calculated from the former by a temporal integration. Such derivations of the Feynman-alpha formula, using also a heuristic derivation of the Rossi-alpha formula, can be found in the literature (Yamane and Pázsit 1998; Baeten 2004).

2.2.3 The Bennett Variance Method

The Bennett variance method (Bennett 1981) utilizes the fact, mentioned above, that the detector counts in repeated time intervals are not independent random variables; for example, the covariance of the counts in neighbor or second neighbor intervals is larger than zero. This fact can be used to construct a measurement method and corresponding formula that can be used as a complement to the Feynman- and Rossi-alpha methods. Namely, the Bennett formula, similarly to the above two, expresses a higher moment of the detection statistics in terms of the reactivity and the delayed neutron precursor fraction, but in a functionally different form. The information content is equivalent with the Feynman- and Rossi-alpha methods, but the application has some practical advantages.

The principle of the method is to define adjacent nonoverlapping time intervals of length τ , separated by the time instants lying at $m\tau$. In the measurement, counts from two different detectors are used, indexed by $i = 1, 2$. Denoting the detector counts in detector i in the interval $(m-1)\tau \leq t \leq m\tau$ as $C_m^{(i)}(\tau)$, first the estimate of the expectation is defined as

$$\langle C^{(i)}(\tau) \rangle = \frac{1}{M} \sum_{m=1}^M C_m^{(i)}(\tau) \quad (61)$$

Next, a quantity called the “local fluctuation” is defined as

$$\delta u_m^{(i)}(\tau) = \frac{C_m^{(i)}(\tau) - \frac{1}{2} \{C_{m-1}^{(i)}(\tau) + C_{m+1}^{(i)}(\tau)\}}{\langle C^{(i)}(\tau) \rangle} \quad (62)$$

The covariance $\sigma_{1,2}^2(\tau)$ is then defined as

$$\sigma_{1,2}^2(\tau) = \frac{1}{M-2} \sum_{m=2}^{M-1} \{ \delta u_m^{(1)}(\tau) \cdot \delta u_m^{(2)}(\tau) \} \quad (63)$$

The evaluation of the right-hand side of (63) requires calculation of the joint expectations $\langle C_k^{(i)}(\tau) C_l^{(i)}(\tau) \rangle$ with $l = k-1, k, k+1$. These are available from Yamane et al. (1999) and were also calculated in Pázsit and Pál (2008). After straightforward but lengthy calculations one obtains the expression

$$\sigma_{1,2}^2(\tau) = \frac{D_{v_p}}{F \left(\frac{\beta}{1-\beta} \right)^2 (1+\$)^2 \tau} \left\{ \frac{3}{2} - \frac{10 - 15e^{-\alpha\tau} + 6e^{-2\alpha\tau} - e^{-3\alpha\tau}}{4\alpha\tau} \right\} \quad (64)$$

where D_{v_p} is the Diven factor of the prompt neutrons, defined in (48), and F is the mean fission rate. By determining the dependence of the Bennett covariance $\sigma_{1,2}^2(\tau)$ on the gate length τ in a measurement and fitting the measurement to (64), the coefficient

$$A_0 = \frac{D_{v_p}}{F \left(\frac{\beta}{1-\beta} \right)^2 (1+\$)^2} \quad (65)$$

can be determined. From A_0 , in possession of the fission rate F and the subcritical reactivity in dollars, $\$$, which can be determined from the same measurement with the Feynman- or Rossi-alpha methods, as well as knowing the Diven factor, the effective delayed neutron fraction β can be determined. Having determined $\$$ and β , the reactivity ρ can also be obtained in absolute units.

A modified version of the Bennett method was proposed and tested by Yamane et al. (1999) and was shown to have advantages over the original Bennett method. The modified version is an extension of the original one by using more time intervals in the definition of the local fluctuation as

$$\delta u_m^{(i)}(\tau) = \frac{C_m^{(i)}(\tau) - \frac{1}{2K} \left\{ \sum_{k=1}^K [C_{m-k}^{(i)}(\tau) + C_{m+k}^{(i)}(\tau)] \right\}}{\langle C^{(i)}(\tau) \rangle} \quad (66)$$

With this, the covariance is now defined as

$$\sigma_{1,2}^2(\tau) = \frac{1}{N-2K} \sum_{m=K+1}^{N-K} \left\{ \delta u_m^{(1)}(\tau) \cdot \delta u_m^{(2)}(\tau) \right\} \quad (67)$$

The τ dependence of the covariance $\sigma_{1,2}^2(\tau)$ of (67) is similar to, but more involved than that of (64). Nevertheless, the value of the coefficient A_0 remains the same as in (65), and can be determined similarly, that is, by fitting the measured data to the theoretical expression.

The original Bennett method has the advantage of being insensitive to a slow drift in the expectations (reactor power) due to the definition of the local fluctuations. The modified Bennett method, while keeping this advantage, is also more robust for low-frequency oscillations.

2.2.4 Mogilner's Zero Crossing Method

This is yet another technique for the determination of the prompt neutron decay constant α from the statistics of neutron detection. Mogilner suggested an expression for the generating function of the probability distribution $P_M(Z, t)$ of detecting Z neutrons during time t such that $P_M(Z, t)$ is a special negative binomial distribution (Mogilner and Zolotukhin 1961). Hence his heuristic generating function

$$G_M(z, t) = \sum_{Z=0}^{\infty} P_M(Z, t) z^Z \quad (68)$$

was of the form

$$G_M(z, t) = [1 + (1-z)\psi(t)]^{-Z(t)/\psi(t)} \quad (69)$$

where $Z(t)$ is the expectation of the neutron counts, given by (22), and $\psi(t) = Y f(t)$ is equal to the prompt term of the Feynman-alpha expression given by the combination of (43) and (46). This can be written as

$$\psi(t) = \varepsilon \left(\frac{\lambda_f}{\alpha} \right)^2 \langle v_p \rangle^2 D_{v_p} \left(1 - \frac{1 - e^{-\alpha t}}{\alpha t} \right) \quad (70)$$

The first two factorial moments of this expression are equal to those of the exact solution.

The essence of the Mogilner method is to utilize an expression for the dependence of the probability of obtaining no counts in a time interval t on the length of this interval. From (69), one obtains

$$P_M(0, t) = G_M(0, t) = [1 + \psi(t)]^{-Z(t)/\psi(t)} \quad (71)$$

and from here it follows that

$$\ln \frac{1}{P_M(0, t)} = Z(t) \frac{\ln [1 + \psi(t)]}{\psi(t)} \quad (72)$$

The use of this formula in measurements is analogous to that of the Feynman-alpha method. The zero detection probability $P_M(0, t)$ is estimated by repeated measurements with a given measurement time and the time-dependence is determined by repeating the procedure with varying the measurement time. After that $\psi(t)$, or rather the prompt neutron decay constant α is determined by a curve-fitting procedure using (72) and (70).

It has to be kept in mind that (71) is only approximately valid. Comparing with the exact expression for the zero detection probability shows that (71) is accurate only if $Y \ll 1$. On the other hand, determination of Y is difficult for such cases. Hence, one has to exercise care with the use of this method.

2.2.5 The Cf-252 Method

This method is different from the above methods, which are all based on pulse counting techniques in the time domain, in that it is based on spectral features of the detector signals in the frequency domain (Mihalcz et al. 1990). A detailed description of all aspects of the method is found in a recently published tutorial (Blakeman 2009), which contains a very extensive list of original publications. Here only a very brief summary is given.

The essence of the method is to use a ^{252}Cf neutron source, which is built together with an ionization chamber. The ^{252}Cf is brought up electrochemically on one of the plates of a parallel-plate ionization chamber. Such an arrangement is called a “ ^{252}Cf detector.” The detector identifies each spontaneous fission event leading to neutron emission by measuring the ionized fission products, but without absorbing any neutron. This way, the time origin of the fission is known, and correlated neutrons can be easily discriminated, and hence an increased signal-to-noise ratio can be obtained.

In the method three detectors are used: one Cf-252 detector (detector #1), and two “ordinary” neutron detectors (#2 and #3) that measure the time-dependent flux fluctuations in current mode. The Cf-252 detector only detects the fission events, which lead to the emission of neutrons (► Fig. 4).

The Cf-252 method also starts with pulse counting and rejecting the pulses of the Cf-252 detector arising from reactions other than spontaneous fission, most notably alpha decay. However, after that the pulses are smoothed by low-pass filtering to a continuous signal, similar to a detector signal in current mode. This signal is then digitized and processed with frequency analysis methods, similar to the methods of power reactor noise, as described in ► Sects. 3–5. The principle of the method is to calculate the pairwise cross-spectra between all three detectors and the auto-spectrum of the Californium detector in the frequency domain.

Figure 4

Schematics of the Cf-252 reactivity measurement method (From Blakeman 2009)

In the original applications of the method (Mihalcz 1990), the multiplication factor is obtained from the following expression:

$$\frac{G_{12}^* G_{13}}{G_{11} G_{23}} = \frac{\nu_c}{\nu} \frac{I_c}{I} \frac{1}{RD_\nu} \frac{1 - k_{eff}}{k_{eff}} \quad (73)$$

Here, G_{12} is the cross-spectrum between detector #1 (containing the Cf source) and detector #2, etc.; ν_c and ν are the mean value of source (Cf) and core (U-235) fission neutrons per fission; I_c and I , the average importance of source and fission chain neutrons; D_ν is the Diven factor of the fission chain prompt neutrons (the same as (48)); finally, R is a factor that corrects for deviations from point kinetics.

The quantities on the left-hand side are measured. The quantities on the right-hand side are either nuclear constants or flux-type quantities that need to be calculated in advance, except k_{eff} . The source strength and detector efficiencies do not appear in the expression. The method yields the absolute value of k_{eff} , that is, not in dollars. However, the knowledge of certain parameters, notably I , I_C and R , is assumed. These need to be determined from transport calculations which, as discussed in the foregoing, in a general case cannot be exact, since the core configuration is only known in an approximate way. However, use of the corrections usually improves the accuracy of the method, even when the correction factors are calculated with a certain inaccuracy.

As described by Blakeman (2009), the method has lately been used in a modified form. The left-hand side of equation (73) is defined as the spectral ratio $R(\omega)$ (independent of the frequency in the frequency range of interest), and the relationship between the spectral ratio and the reactivity is written as

$$R(\omega) = R = \frac{\rho}{C_2\rho - C_1}$$

where C_1 and C_2 are constants, consisting of the Diven factors of the Cf-252 fission and that of the fissile material as well as detector efficiencies and fission rates. For reactivities close to critical, $C_2\rho - C_1 \approx -C_1$, moreover $C_1 \approx 1$, hence for such cases, the spectral ratio is approximately equal to the subcritical reactivity.

The method has some advantages over other methods. It does not require the knowledge of β and Λ . This is sometimes expressed such as no calibration close to delayed critical is necessary. The method is fast, such that a short measurement period (a few seconds) is sufficient for a reliable measurement. Thus, the method can be applied on-line (following dynamic changes in the reactivity) and it works also with deep subcriticalities. For the same reasons, the method can be used in large cores. Currently, this is the only method that is effective for reactivity control in power reactor cores during loading. A recent application is reported by Baeten et al. (2010), which also discusses the principles of the technique.

2.3 Reactivity Measurements in ADS

The neutron fluctuation-based methods of measuring subcritical reactivity described earlier have been elaborated and tested a long time back. However, recently these methods have received a renewed attention due to the appearance of the concept of accelerator-driven subcritical systems (ADSs). In these systems, various methods of reactivity measurement were investigated both conceptually as well as in some experimental programs. Regarding the Rossi- and Feynman-alpha methods, these needed some theoretical development. In contrast to the traditional methods that use a neutron source with pure Poisson statistics, the neutron source in an ADS, based on the spallation process, has a so-called compound Poisson statistics with a time-dependent source intensity. The first characteristic, that is, the compound Poisson statistics, is due to the fact that several source neutrons are generated simultaneously in each spallation event, whose descendants have the same temporal correlation properties as neutrons belonging to the same fission chain. The second characteristic, the temporal intensity, arises since the accelerator, serving as the neutron source, is usually run in a pulsed mode, that is, with a periodically varying intensity. Hence the process is not stationary, only periodically stationary in such systems.

Because of these differences in the source properties, the corresponding Rossi- and Feynman-formulas will be modified as compared to their traditional counterparts in the literature. In this section, an account will be given of the formulas used in ADS experiments.

2.3.1 Spallation Source

In the target of a spallation source, a large and random number of neutrons (typically several tens of neutrons) are generated by each impinging high-energy proton. In a thick target, a whole shower of spallation reactions will take place. It is usually assumed that the target is small enough such that all neutrons in one reaction can be assumed as being born simultaneously. Such sources will be called multiple emission sources. Actually, a Cf-252 source is also a multiple emission source, but the effects of its relatively low multiplicity are negligible.

The number of spallation events in a time interval for a steady source with a constant intensity S will be assumed to follow Poisson statistics. The validity of this assumption is questionable; there is reason to believe that the ions (protons) of an accelerator are time-correlated. This question is discussed in detail by Degweker and Rana (2007) who derive formulas for certain forms of time-correlations between the accelerator ion impinging events. We shall disregard such effects here.

The distribution of the number of particles emitted per spallation event will be denoted by $p_q(n)$, and its generating function will be denoted as

$$r(z) = \sum_{n=0}^{\infty} p_q(n) z^n. \quad (74)$$

Only the first two moments of the above distribution will enter the relevant final formulas, and these will be denoted as

$$r_1 = \langle \mathbf{q} \rangle = \sum_n n p_q(n) \quad \text{and} \quad r_2 = \langle \mathbf{q}(\mathbf{q} - 1) \rangle = \sum_n n(n-1) p_q(n). \quad (75)$$

It is practical to introduce the Diven factor of the source:

$$D_q = \frac{\langle \mathbf{q}(\mathbf{q} - 1) \rangle}{\langle \mathbf{q} \rangle^2} = \frac{r_2}{r_1^2}. \quad (76)$$

Since the difference compared to the traditional case lies entirely in the different statistics of the source, the distributions induced by a single particle will not be affected. Hence it is only the formula connecting the single-particle induced and source-induced distributions, which has to be recalculated; the rest of the calculations will go along a line very similar to that given previously for the backward approach. With the same arguments as with (24), one can write, in first order of dt :

$$P(N, C, Z, T, t) = (1 - S dt) P(N, C, Z, T, t - dt) + S dt \sum_{n, c, z} P(N - n, C - c, Z - z, T, t) \sum_k p_q(k) A_k(n, c, z, T, t), \quad (77)$$

where, analogous to (30), the function $A_k(n, c, z, T, t)$ is defined as

$$A_k(n, c, z, T, t) = \sum_{\substack{n_1 + \dots + n_k = n \\ c_1 + \dots + c_k = c \\ z_1 + \dots + z_k = z}} \prod_{j=1}^k p(n_j, c_j, z_j, T, t). \quad (78)$$

With the usual steps, the solution of the equation connecting the corresponding generating functions of the single-particle induced distribution and that of the source-induced distribution reads as

$$G(x, y, v, T, t) = \exp \left\{ S \int_0^t \{ r[g(x, y, v, T, t')] - 1 \} dt' \right\}. \quad (79)$$

This expression is very similar to the case of a simple Poisson source, (27), except that the single-particle generating function appears as an argument of a power series represented by the generating function $r(z)$ of the source particle number distribution. The form of the relationship is not affected by the presence of delayed neutrons or detectors in the system; those only affect $p(n, c, z, T, t)$, but not the source properties.

Due to the similarity with the formulas for the standard case, and the unchanged form of the single-particle induced distribution, it can be expected that the Feynman- and Rossi-alpha for the case of the spallation source will only be moderately changed compared to the traditional formulas. This is indeed the case. Without the details of the calculations, we quote here the results.

It turns out that the Feynman-alpha formula can be written exactly in the same form as (41), that is,

$$Y(t) = \varepsilon \frac{\lambda_f^2}{(\alpha + \lambda)} \sum_{i=1}^2 \frac{W(\alpha_i)}{(\alpha_i - \alpha_j)} f_i(t); \quad i, j = p, d; i \neq j \quad (80)$$

where, as in the traditional case, the limit $t \rightarrow \infty$ was performed and the measurement time duration T was re-denoted as t . The parameters α_p, α_d and the functions $f_p(t)$ and $f_d(t)$ are the same as before, for example, in (45). The only difference is that the function $W(s)$ is now modified to

$$W(s) = \left(1 - \frac{\lambda^2}{s^2} \right) \left[\langle v_p(v_p - 1) \rangle + r_2 \frac{\langle v \rangle}{r_1} (-\rho) \right] - \frac{\lambda^2}{s^2} 2 \langle v_p \rangle \langle v_d \rangle. \quad (81)$$

Writing the result again in the standard Feynman $Y(t)$ form

$$Y(t) = \varepsilon \sum_{i=1}^2 A_i f_i(t) \quad (82)$$

and considering the prompt term $\varepsilon A_1 f_1(t)$ only with the same simplifications as in the traditional case, that is, with (46), one obtains

$$\begin{aligned} \varepsilon A_1 f_1(t) &= \frac{\varepsilon D_{v_p}}{(\rho - \beta)^2} \left[1 + \frac{r_1 D_q}{\langle v \rangle D_{v_p}} (-\rho) \right] \left(1 - \frac{1 - e^{-\alpha t}}{\alpha t} \right) \\ &= \frac{\varepsilon D_{v_p}}{(\rho - \beta)^2} (1 + \delta) \left(1 - \frac{1 - e^{-\alpha t}}{\alpha t} \right). \end{aligned} \quad (83)$$

Here the parameter

$$\delta = \frac{r_1 D_q}{\langle v \rangle D_{v_p}} (-\rho) \quad (84)$$

was introduced.

It is thus seen that for multiple emission sources, the variance to mean formula changes only very slightly. The time-dependence of the formula, which is the basis of the reactivity determination, is the same as with a simple Poisson source.

It is seen that the presence of the multiple emission is beneficial for the application of the Feynman method for the measurement of the reactivity, since it increases the amplitude of the useful part of the variance, that is, the factor Y , which stands for the deviation from the Poisson statistics in the count rate. The reason for this is the simultaneous emission of several source neutrons in the system by the source, hereby increasing the number of neutrons being time-correlated.

The effect of the presence of the “enhancement factor” $\delta > 0$ on the formula can be estimated quantitatively. According to experimental evidence, the Diven factors show a very little variation whether it regards fission or spallation, that is, the factor D_q/D_{v_p} will be in the order of unity. For a ^{252}Cf source in a core loaded with enriched uranium, the factor $r_1/\langle v \rangle = \langle \mathbf{q} \rangle / \langle v \rangle$ is also in the order of unity, hence for a value of the multiplication factor $k_{eff} = 0.95$, the correction represented by δ is below 10%. For spallation sources, on the other hand, the situation is different. For spallation with protons in the GeV range and a thick Pb target, the yield is $r_1 \approx 40$ neutrons per spallation event, and accordingly, with $k_{eff} = 0.95$, one has $\delta \approx 3$. For deeper subcriticalities the value increases further. Hence, for deeply subcritical systems the large source multiplicity becomes a significant factor in measuring the reactivity of the system.

For the Rossi-alpha formula with a steady spallation source, the differences to the traditional case are the same as for the Feynman-alpha formula. The Rossi-alpha for the multiple emission source case is given as

$$P_r(\tau) d\tau = \frac{C_{ZZ}(\tau)}{Z dt} = \frac{\epsilon \lambda_f^2 d\tau}{2(\alpha + \lambda)} \sum_{i=1}^2 \frac{W(\alpha_i)}{(\alpha_i - \alpha_j)} f_i(t); \quad i, j = p, d; \quad i \neq j \quad (85)$$

where the function $W(s)$ is equal to those in the Feynman-alpha formula for spallation sources, (81), whereas the functions $f_i(\tau)$ are the same as in the traditional case, (58):

$$f_i(\tau) \equiv \alpha_i e^{-\alpha_i \tau}, \quad i = p, d.$$

Hence the same enhancement factor δ appears in the Rossi-alpha formula for spallation sources as in the Feynman-alpha formula.

2.3.2 Pulsed Source in Feynman- and Rossi-Alpha Applications

For technical reasons, accelerator-driven subcritical systems will be most likely run in a pulsed mode. At least this has been the case in some model ADS experiments performed so far.

When considering the description of the source in a pulsed ADS, there are a large number of varieties. The pulsing itself can be treated as strictly periodic. The pulses can be either wide or narrow, on a time scale of the lifetime of the subcritical chains in the core. For wide

pulses, the source events within the pulse can be treated either as a Poisson point process, or to be time-correlated with an exponentially decaying correlation. Various pulse forms can be assumed, the square and the Gaussian distribution of the temporal intensity of the source being two possibilities that have been considered.

For very narrow pulses, it is a good approximation that all neutrons in the pulse are emitted simultaneously. The case of narrow pulses can be described much simpler by assuming strongly periodic processes for the injection, that is, a train of temporal Dirac-delta functions. This is equivalent with the assumption that all neutrons in the short pulse were born concurrently. There is a principal difference between source neutrons born simultaneously in an instantaneous emission, or being born in a finite width pulse with either correlated or uncorrelated statistics of the neutrons being born in the pulse.

A final distinction between further alternatives is whether the pulsing is synchronized with the start of the data collection in the experiment or not. In the latter case, the start of the neutron counting is a random parameter in relation to the pulse starting times. These two alternatives will be referred to as “deterministic pulsing” (detection start synchronized with the pulses) and “stochastic pulsing,” respectively.

Due to the above variety, there is a corresponding collection of Feynman- and Rossi-alpha formulas (Degweker 2000, 2003; Yamane et al. 2002; Kitamura et al. 2005; Ballester and Munoz-Cobo 2005; Munoz-Cobo et al. 2008). A generic and most complete treatment of all cases is given by Degweker and Rana (2007) and we refer the reader to that publication for details. Here we shall only give results for the case of narrow pulses. For the sake of better readability, the delayed neutrons will be neglected and we shall only consider the prompt part of the corresponding Feynman- and Rossi-alpha formulas. The extension to include delayed neutrons is readily possible and is available in the literature.

2.3.3 Feynman-Alpha with Deterministic Pulsing

Here it is assumed that pulses are emitted into the system at times $t = nT_0$, with n running through the integers from $-\infty$ to ∞ . The measurement starts at $t = +0$, and lasts over a gate length T , hence its start coincides with the arrival of a pulse (this case is also called the “pulse-triggered” Feynman-alpha measurement). It is supposed that in one pulse a random number of neutrons are injected with a probability distribution $p_q(n)$, with a corresponding generating function $r(z)$, that is, the same notations are used as before.

The final result for the deterministically pulsed Feynman-alpha formula reads as

$$Y(T) = \frac{\lambda_d \lambda_f \langle v(v-1) \rangle}{\alpha^2 M_1^*(T)} \left\{ \frac{-2\alpha u e^{-\alpha u} + 2(1 - e^{-\alpha T})}{1 - e^{-\alpha T_0}} - \frac{2\alpha T_0 e^{-\alpha T_0} (e^{-\alpha u} - e^{-\alpha T})}{(1 - e^{-\alpha T_0})^2} + (1 + \delta^*) [T/T_0] - (1 - \delta^*) \frac{e^{-2\alpha u} - e^{-2\alpha T} + (1 - e^{-\alpha T})^2}{1 - e^{-2\alpha T_0}} - \delta^* \frac{2(e^{-\alpha u} - e^{-\alpha T})}{(1 - e^{-\alpha T_0})} \right\}. \quad (86)$$

with

$$M_1^*(T) = \frac{1 + [T/T_0] (1 - e^{-\alpha T_0}) - e^{-\alpha u}}{1 - e^{-\alpha T_0}} \quad (87)$$

Here, $[T/T_0]$ stands for the largest integer smaller than or equal to T/T_0 , $u = T - [T/T_0]T_0$, $\alpha = \alpha_p$ is the prompt neutron decay constant, and $M_1^*(T)$ is proportional to the first moment of the detector counts. Further, δ^* is a “source enhancement factor”:

$$\delta^* \equiv \frac{r_1}{\langle v \rangle} \frac{(D_q - 1)}{D_v} |\rho| = \delta - \frac{r_1 |\rho|}{\langle v \rangle D_v} \quad (88)$$

Its form is similar to the factor δ , defined in (84). The difference is that instead of the factor D_q , the expression $D_q - 1$ appears in the numerator.

2.3.4 Feynman-Alpha with Stochastic Pulsing

Here it is assumed that the arrival of the pulses and the start of the measurement are not synchronized. As a result, the corresponding formulas, and in particular that of the expectation of the detector counts, will be smoother functions of time. The result is given as

$$Y(T) = \frac{\lambda_d \lambda_f \langle v(v-1) \rangle}{\alpha^2} [1 + \delta^*] \left(1 - \frac{1 - e^{-\alpha T}}{\alpha T} \right) + \frac{r_1 \lambda_d}{\alpha} \left\{ \frac{u(T_0 - u)}{T_0 T} + \frac{e^{\alpha(u-T_0)} + e^{-\alpha u} - e^{-\alpha T_0} - 1}{\alpha T (1 - e^{-\alpha T_0})} \right\}. \quad (89)$$

The factor δ^* is the same as in (88). This expression consists of two terms; a smooth term, corresponding to the traditional Feynman-alpha solution with stationary sources, although with an amplitude enhanced with the factor δ^* , and a nonnegative oscillating term with an oscillation period equal to T_0 . The smooth, traditional term constitutes a lower envelope of the oscillatory part. This formula is suitable for evaluating measurements, and was experimentally verified.

2.3.5 Rossi-Alpha with Stochastic Pulsing

Again, without details of the derivation, the final result is given as

$$R(\tau) = \frac{P_2(0, \tau)}{Z} = \frac{\lambda_d \lambda_f \langle v(v-1) \rangle}{2\alpha} [1 + \delta^*] e^{-\alpha \tau} + \frac{r_1 \lambda_d}{\alpha T_0} + \frac{r_1 \lambda_d}{2(1 - e^{-\alpha T_0})} \left[e^{-\alpha u} + e^{-\alpha T_0} e^{\alpha u} - \frac{2(1 - e^{-\alpha T_0})}{\alpha T_0} \right] \quad (90)$$

The result contains a traditional smooth Rossi-alpha formula, that is, a decaying exponential and a constant part corresponding to the so-called correlated and uncorrelated counts, plus an oscillating part. The oscillating part has a discontinuous derivative, unlike in the case of the stochastically pulsed Feynman-alpha curve. As the formula shows, in contrast to the pulsed Feynman-alpha method, the oscillations do not decay with time; rather they are periodic. This lends the possibility of eliminating the oscillating part from an experiment, from the tail of the curve at large τ values (Kitamura et al. 2006).

2.4 Pulse Counting Techniques in Nuclear Material Management (Safeguards)

Branching in the fission process, as the physical origin of time correlations and hence nontrivial statistical properties of the neutron distribution, can be used also in areas other than measuring the reactivity (or multiplication factor) in nearly critical systems. One such area, a branch of nuclear safeguards, deals with nuclear material control and accounting. The purpose is to detect, identify, and quantify fissile material with nonintrusive methods (Böhnel 1985; Hage and Cifarelli 1985; Ensslin 1998). This is achieved by detecting radiation, either neutrons or gamma photons, that are emitted either spontaneously (passive methods), or through inducing by neutron or photon irradiation (active methods).

As a rule, such investigations concern samples of fissile material far from being critical. The material, consisting of transuranic elements, is a neutron emitter through spontaneous fission or emission through (α, n) reaction, and the passive way of identification is based on detecting the emitted neutrons, and lately also the associated gamma photons (Pázsit and Pozzi 2005). However, even in small samples, a primary neutron has a nonzero probability to start a short chain before escaping through fission induced in the sample, much like in the case of fast fission in the fuel elements of thermal reactors. The difference in the number and energy distributions in spontaneous and induced fission between the different isotopes gives, theoretically, a possibility of identifying the fissile isotope, and also its mass. In practice, with present technology, only some lumped parameters can be determined. The most relevant material to be quantified is plutonium, and the measurements supply the so-called ^{240}Pu effective mass. The total Pu mass is then extracted from the ^{240}Pu mass by determining the isotopic composition of the sample by other means such as gamma-ray spectroscopy.

Here we only consider the number distributions and will disregard the energy aspects. The number distribution of the fission neutrons is usually quantified by the low-order factorial moments. These are then converted into multiplicity detection rates, which are the quantities observed in measurements. In the safeguards literature, the number of neutrons or gamma photons in a spontaneous fission, as well as the number of particles generated or leaving the sample is often referred to as multiplicities, and the various descriptors as multiplicity distribution, multiplicity moments, etc. For example, experimental determination of the factorial moments is usually referred to as “multiplicity counting.” Whenever it cannot lead to confusion, any of these quantities may be referred to as just multiplicities.

In what follows, the notations used will be briefly summarized, and the master equations for the generating function of the number of neutrons and gamma photons per one initial neutron and one initial source event (spontaneous fission) will be given. After that, without derivation, a mere list of the factorial moments is given, together with the corresponding multiplicity detection rates.

The notations are summarized as follows. Random variables and their moments referring to neutrons are denoted by ν , their probability distributions by $p(n)$, and their generating functions by $q(z)$. The same quantities for gamma photons are denoted by μ , $f(n)$, and $r(z)$. The variables/moments and the number distributions belonging to (known) elementary nuclear reactions, will have indices, indicating which type of reaction they refer to. Those referring to spontaneous fission will have a subscript sf , and those referring to induced fission will have a subscript i . For the factorial moments, there will always be a second index, giving the order of the moment, such as $\nu_{sf,2}$.

In addition, one has to distinguish between two sets of variables for both neutrons and photons, depending on whether they belong to a source event (all processes, i.e., spontaneous fission and (α, n) processes included), or to the *total number* of generated neutrons, which accounts also for the internal multiplication (“superfission.” After Böhnel 1985). The parameters belonging to the first set will be written with a subscript indication (*sf*, *i* or *s*, the latter denoting “source”), whereas those of the second set will be denoted with just a numerical subscript indicating their order. The corresponding probability distributions will be denoted by $p(n)$ and $P(n)$ for neutrons, for the total number of neutrons per one starting neutron or one source event, respectively, and by $f(n)$ and $F(n)$ for gamma photons, respectively. The corresponding generating functions are denoted by $h(z)$, $H(z)$, $g(z)$, and $G(z)$, respectively. Finally, the probability that a neutron will have a collision before escaping will be denoted by the symbol p . This latter parameter is not known in a measurement, hence it is one of the parameters to be determined.

The relationship between the number distribution of the source neutrons, $p_s(n)$, which accounts for both spontaneous fission and (α, n) neutrons, and that of the number distribution of spontaneous fission, $p_{sf}(n)$, is given by

$$p_s(n) = \frac{\alpha v_{sf} \delta_{1,n} + p_{sf}(n)}{1 + \alpha v_{sf}} \quad (91)$$

where the parameter α is defined as the ratio of the average neutron production between (α, n) and spontaneous fission processes:

$$\alpha = \frac{Q_\alpha}{Q_f v_{sf}} \quad (92)$$

Here, Q_α and Q_f are the intensities of the corresponding processes. The introduction of the joint source distribution (91) simplifies the notations while doing the calculations, but in the end one has to go back to the distribution $p_s(n)$ and its moments, since the distribution $p_s(n)$ contains the factor α , which is not known and hence need to be determined together with the other parameters sought, from the detected multiplicity rates.

From the nature of the problem, it follows that the master equations to be derived for the probability distribution of the neutrons or photons leaving the sample has to be a backward type equation. Hence, as described earlier in this chapter, it has to be split into the task of calculating the number distribution of particles leaving the sample as generated by one starting neutron, and by one source event, respectively. Let $w(n_1, n_2)$ denote the probability of *one* starting neutron leading to n_1 neutrons and n_2 gamma photons, and $u(z_1, z_2)$ its generating function. Likewise, let $W(n_1, n_2)$ and $U(z_1, z_2)$ denote the same quantities for one *source* event. Then, by simple considerations it is easy to derive the following master equations for the generating functions (for the details, see Pázsit and Pál 2008):

$$u(z_1, z_2) = (1 - p)z_1 + pr_i(z_2)q_i[u(z_1, z_2)] \quad (93)$$

where $q_i(z)$ and $r_i(z)$ are the generating functions of the number distributions of neutrons and photons generated in an induced reaction, respectively, and

$$U(z_1, z_2) = r_s(z_2)q_s[u(z_1, z_2)]. \quad (94)$$

Equations (93) and (94), together with (91) are fully sufficient to derive individual and mixed factorial moments for the neutrons and gamma photons. The separate equations for neutrons and gamma photons only, which are better known from the literature, can be obtained by substituting $z_1 = 1$ and $z_2 = 1$, respectively. These read for the corresponding generation functions, with the notations defined earlier, as

$$h(z) = (1 - p)z + pq_r [h(z)], \quad (95)$$

$$H(z) = q_s [h(z)] \quad (96)$$

for the neutrons, and

$$g(z) = (1 - p) + pr_r(z)q_r [g(z)], \quad (97)$$

$$G(z) = r_s(z)q_s [g(z)] \quad (98)$$

for the gamma photons.

In what follows, without derivation, we list here the first three individual factorial moments for neutrons and gamma photons, and the first three mixed moments (for the derivation of the full probability distributions see Enqvist et al. 2006).

2.4.1 Neutron Factorial Moments

One defines the so-called *leakage multiplication* as

$$\mathbf{M} \equiv \frac{1 - p}{1 - pv_{i,1}}; \quad pv_{i,1} < 1 \quad (99)$$

With this notation, the moments for the singles, doubles, and triples read as

$$v_1 = \mathbf{M}v_{s,1} \quad (100)$$

$$v_2 = \mathbf{M}^2 \left\{ v_{s,2} + \frac{\mathbf{M} - 1}{v_{i,1} - 1} v_{s,1}v_{i,2} \right\} \quad (101)$$

$$v_3 = \mathbf{M}^3 \left\{ v_{s,3} + \frac{\mathbf{M} - 1}{v_{i,1} - 1} (3v_{s,2}v_{i,2} + v_{s,1}v_{i,3}) + 3 \left(\frac{\mathbf{M} - 1}{v_{i,1} - 1} \right)^2 v_{s,1}v_{i,2}^2 \right\} \quad (102)$$

2.4.2 Gamma Photon Factorial Moments

One defines the gamma leakage multiplicity per one initial neutron

$$\mathbf{M}_y \equiv \frac{p\mu_{i,1}}{1 - pv_{i,1}} \quad (103)$$

and the factorial moments g_n of the number of gamma photons generated by one initial neutron,

$$g_n = \left. \frac{d^n g(z)}{dz^n} \right|_{z=1} \quad (104)$$

Then the moments read as follows:

$$\mu_1 = \frac{\mu_{sf,1} + \alpha v_{sf,1}}{(1 + \alpha v_{sf,1})} + \frac{v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} \mathbf{M}_\gamma, \quad (105)$$

$$\mu_2 = \frac{\mu_{sf,2}}{1 + \alpha v_{sf,1}} + 2 \frac{(\mu_{sf,1} + \alpha v_{sf,1})}{(1 + \alpha v_{sf,1})} \frac{v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} \mathbf{M}_\gamma + \frac{v_{sf,2}}{(1 + \alpha v_{sf,1})} \mathbf{M}_\gamma^2 + \frac{v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} g_2 \quad (106)$$

and

$$\begin{aligned} \mu_3 = \frac{1}{(1 + \alpha v_{sf,1})} & \left[\mu_{sf,3} + 3 \mu_{sf,2} \frac{v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} \mathbf{M}_\gamma \right. \\ & + 3(\mu_{sf,1} + \alpha v_{sf,1}) \left\{ \frac{v_{sf,2}}{(1 + \alpha v_{sf,1})} \mathbf{M}_\gamma^2 + \frac{v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} g_2 \right\} \\ & \left. + v_{sf,3} \mathbf{M}_\gamma^3 + 3 v_{sf,2} g_2 + v_{sf,1}(1 + \alpha) g_3 \right] \quad (107) \end{aligned}$$

with

$$g_2 = \frac{\mathbf{M} - 1}{v_{i,1} - 1} \{ \mu_{i,2} + 2 \mu_{i,1} v_{i,1} \mathbf{M}_\gamma + v_{i,2} \mathbf{M}_\gamma^2 \} \quad (108)$$

and

$$g_3 = \frac{\mathbf{M} - 1}{v_{i,1} - 1} \{ \mu_{i,3} + 3 \mu_{i,2} v_{i,1} \mathbf{M}_\gamma + 3 \mu_{i,1} [v_{i,2} \mathbf{M}_\gamma^2 + v_{i,1} g_2] + v_{i,3} \mathbf{M}_\gamma^3 + 3 v_{i,2} \quad (109)$$

In (105) the possibility of generating single photons in an (α, n) reaction was taken into account.

2.4.3 Mixed Moments

$$\langle v \mu \rangle = \frac{1}{(1 + \alpha v_{sf,1})} \left[\frac{(\mu_{sf,1} + \alpha v_{sf,1}) v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} \mathbf{M} + v_{sf,2} \mathbf{M} \mathbf{M}_\gamma + v_{sf,1}(1 + \alpha) c_{1,1} \right] \quad (110)$$

$$\begin{aligned} \langle v(v-1) \mu \rangle = \frac{1}{(1 + \alpha v_{sf,1})} & \left\{ (\mu_{sf,1} + \alpha v_{sf,1}) \left[\frac{v_{sf,2}}{(1 + \alpha v_{sf,1})} \mathbf{M}^2 + \frac{v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} h_2 \right] \right. \\ & \left. + v_{sf,3} \mathbf{M}_\gamma \mathbf{M}^2 + v_{sf,2} [2 \mathbf{M} c_{1,1} + \mathbf{M}_\gamma h_2] + v_{sf,1}(1 + \alpha) c_{2,1} \right\} \quad (111) \end{aligned}$$

and

$$\begin{aligned} \langle v \mu(\mu-1) \rangle = \frac{1}{(1 + \alpha v_{sf,1})} & \left\{ \mu_{sf,2} \frac{v_{sf,2}}{(1 + \alpha v_{sf,1})} \mathbf{M} \right. \\ & + 2(\mu_{sf,1} + \alpha v_{sf,1}) \left[\frac{v_{sf,2}}{(1 + \alpha v_{sf,1})} \mathbf{M} \mathbf{M}_\gamma + \frac{v_{sf,1}(1 + \alpha)}{(1 + \alpha v_{sf,1})} c_{1,1} \right] \\ & \left. + v_{sf,3} \mathbf{M} \mathbf{M}_\gamma^2 + v_{sf,2} [g_2 \mathbf{M} + 2 \mathbf{M}_\gamma c_{1,1}] + v_{sf,1}(1 + \alpha) c_{1,2} \right\} \quad (112) \end{aligned}$$

Here the following abbreviations were introduced:

$$c_{1,1} = \left\{ p \frac{\mu_{i,1} \nu_{i,1} \mathbf{M} + \nu_{i,2} \mathbf{M} \mathbf{M}_\gamma}{1 - p \nu_{i,1}} \right\}, \quad (113)$$

$$c_{2,1} = \frac{p}{1 - p \nu_{i,1}} \{ \mu_{r,1} [\nu_{i,2} \mathbf{M}^2 + \nu_{i,1} h_2] + \nu_{i,3} \mathbf{M}^2 \mathbf{M}_\gamma + \nu_{i,2} [h_2 \mathbf{M}_\gamma + 2 \mathbf{M} c_{1,1}] \}, \quad (114)$$

$$c_{1,2} = \frac{p}{1 - p \nu_{i,1}} \{ \mu_{i,2} \nu_{i,1} \mathbf{M} + 2 \mu_{i,1} [\nu_{i,2} \mathbf{M} \mathbf{M}_\gamma + \nu_{i,1} c_{1,1}] + \nu_{i,3} \mathbf{M} \mathbf{M}_\gamma^2 + \nu_{i,2} [2 \mathbf{M}_\gamma c_{1,1} + \mathbf{M} g_2] \} \quad (115)$$

and

$$h_2 = \frac{\mathbf{M} - 1}{\nu_{i,1} - 1} \nu_{i,2} \mathbf{M}^2. \quad (116)$$

2.4.4 Multiplicity Detection Rates

The multiplicity detection rates can be calculated by defining the intensity of the source events by introducing the sample fission rate F , and the detection efficiencies ε_n and ε_γ for the neutrons and photons, respectively. The total source event intensity Q_s can be expressed by the fission rate F and the factor α as

$$Q_s = F + Q_\alpha = F(1 + \alpha \nu_{sf,1}) \quad (117)$$

It is easy to see that the intensity C_k of detecting the k th order multiplets, by accounting for all possible combinations of selecting a k -tuple from a higher-order multiplet and for the detection efficiency, is given by

$$C_k = Q_s \frac{\varepsilon_n^k \nu_k}{k!} \quad (118)$$

for the neutrons and a similar formula is valid for the gamma photons. Using (117) and (118) together with the expressions for factorial moments and (91), the multiplicity detection rates for the singles, doubles, and triples will read as

$$S = F \varepsilon_n \mathbf{M} \nu_{sf,1} (1 + \alpha), \quad (119)$$

$$D = \frac{F \varepsilon_n^2 \mathbf{M}^2}{2} \left[\nu_{sf,2} + \left(\frac{\mathbf{M} - 1}{\nu_{i,1} - 1} \right) \nu_{sf,1} (1 + \alpha) \nu_{i,2} \right] \quad (120)$$

and

$$T = \frac{F \varepsilon_n^3 \mathbf{M}^3}{6} \left\{ \nu_{sf,3} + \left(\frac{\mathbf{M} - 1}{\nu_{i,1} - 1} \right) [3 \nu_{sf,2} \nu_{i,2} + \nu_{sf,1} (1 + \alpha) \nu_{i,3}] + 3 \left(\frac{\mathbf{M} - 1}{\nu_{i,1} - 1} \right)^2 \nu_{sf,1} (1 + \alpha) \nu_{i,2}^2 \right\}. \quad (121)$$

Similar expressions can be derived for the gamma multiplicity detection rates and the mixed detection rates (Enqvist et al. 2010). Such expressions have been derived recently, but since these are not yet in routine use, they will not be given here.

The three multiplicity detection rates above are used to unfold three parameters of an unknown sample, out of which the sample fission rate, most directly related to the sample mass, is the most important. The other two unknowns are the factor α and the leakage multiplication $\mathbf{M}$, which latter depends on the first collision probability p and hence also on the sample mass, although in a rather implicit manner. This approach assumes that the detection efficiency is the same for all detectors included, and that it is known.

The above equations represent a coupled nonlinear system, which is of fifth order in the leakage multiplication, but can be solved such that at most a third-order algebraic equation needs to be solved. Formally, one has to determine the physical root of the equation

$$a + b\mathbf{M} + c\mathbf{M}^2 + \mathbf{M}^3 = 0 \quad (122)$$

where the coefficients read as

$$a = \frac{-6Tv_{s2}(v_{i1} - 1)}{\varepsilon^2 S [v_{i3}v_{s2} - v_{s3}v_{i2}]} \quad (123)$$

$$b = \frac{2Dv[v_{s3}(v_{i1} - 1) - 3v_{i2}v_{s2}]}{\varepsilon S [v_{i3}v_{s2} - v_{s3}v_{i2}]} \quad (124)$$

and

$$c = \frac{6v_{i2}v_{s2}D}{\varepsilon S [v_{i3}v_{s2} - v_{s3}v_{i2}]} - 1 \quad (125)$$

Having determined $\mathbf{M}$, the other two parameters (F and α) can be easily obtained by substituting it back to (119) (Cifarelli and Hage 1986). In practice, the doubles and triples gate fraction factors f_d and f_t also appear in the formulas, however these are neglected here for simplicity.

Using the gamma and the mixed multiplicity rates for the unfolding of the sample parameters is more complicated, due to the more complicated nonlinear structure of the equations, and to the larger number of unknowns, it is not possible to use analytical tools for the inversion; rather, nonparametric nonlinear unfolding methods are suggested.

3 Power Reactor Noise Theory

Power reactor noise deals with neutron fluctuations that are induced by fluctuations or oscillations of the reactor properties, that is, displacement of core components, temperature, or density variations. It is clear that any temporal change in the reactor composition manifests itself as changes of the corresponding cross sections. These changes are called “perturbations.” The cross sections are, in turn, coefficients of the pertinent transport or diffusion equations. Time-dependence of the cross sections will naturally lead to the time-dependence of the neutron flux, which is in addition space-dependent. Most often the changes in the cross sections are due to processes that are themselves random in character: turbulent one- or two-phase flow, boiling, flow-induced random vibrations, etc. Hence the induced neutron flux variations

will also become random processes in time, with a deterministic, or sometimes random space-dependence (when then perturbation is random in space). One talks about space- and time- (frequency-) dependent neutron noise in power reactors, or about power reactor noise in short. The use of the neutron noise, by unfolding the noise source properties from the measured neutron noise and by knowledge of the effect of the perturbations on the neutron noise (i.e., through knowledge of the reactor transfer function), is called neutron noise diagnostics.

The origin of neutron noise theory can be traced back to the reactor oscillator experiments performed at the “Clinton Pile” in Oak Ridge. The Clinton Pile was the nickname of the first “real” reactor, the Graphite Reactor or X-10 reactor. It was built already in 1943 (after Fermi’s first reactor in Chicago , 1942) in what is today called the Oak Ridge National Laboratory (ORNL). The reactor today is a historic landmark building and is shown in ► Fig. 5.

Such neutron oscillations were first induced artificially in so-called oscillator experiments. These were, at the beginning, not at all about reactor diagnostics, rather just investigations of nuclear physics data (measurement of cross sections). Various samples were moved back and forth inside the core periodically, and the goal of the measurements was to determine thermal absorption cross sections of the various elements. This was achieved by measuring the amplitude of neutron oscillations and comparing it with measurements with samples of known cross sections.

Already then it was observed that the neutron flux fluctuations, that is, the response of the reactor was considerably more complex than solely reactivity-induced power oscillations,

The Graphite Reactor, above, is the only National Historic Landmark on the ORR.

A fuel slug from the reactor is pictured with a commemorative landmark medallion (upper left).

A scientist and workers remove radioactive material from a tray in the Graphite Reactor (lower left).

■ Figure 5

The building of the graphite reactor (right); a fuel piece (top left); and the removal of an irradiated sample from a horizontal channel (bottom left)

that is, a “point-kinetic response,” in which the neutron distribution maintains its spatial form (equal to the critical neutron flux) and only its amplitude changes. Rather, the response was space-dependent, and consisted of a local term with short spatial relaxation that prevailed in the vicinity of the disturbance (10–20 cm), corresponding to the local flux dip movement with the absorber, and a global component, with a much longer spatial relaxation length. In small, tightly coupled reactors, this global component is equal to the reactivity or point reactor component, but in large reactors a further, slowly varying space-dependent component appears. The theoretical analysis of the Clinton Pile measurements was given in a classic paper by Weinberg and Schweinler (1948).

Later, it was observed in the Oak Ridge Research Reactor (ORR) and the high flux isotope reactor (HFIR) that anomalous vibrations of control rods can be identified from the frequency spectrum of in-core neutron detectors (Fry 1971). In measurements performed in the HFIR, suddenly a peak appeared at 5–6 Hz. The reason for this peculiar frequency-dependence was that a ball bearing to one of the control rods had been broken and the control rod started excessive flow-induced vibrations with this frequency.

This event made it clear that it was possible to obtain information about unwanted or unexpected changes or anomalies by measuring neutron fluctuations in the core. This is how the concept of neutron noise diagnostics was born. Later, similar observations were made in power plants. It was observed in the Palisades plant (USA) that vibrations of the whole core barrel and its support can be detected by ex-core neutron detectors (Fry et al. 1974). German measurements in boiling water reactors (BWRs) showed a linear phase of the coherence between two detectors in the same detector tube, showing the velocity of the two-phase flow (Wach and Kosály 1974). Vibrations of such detectors in BWRs were also detected and quantified by neutron noise methods. Control rod vibrations were observed and the vibrating rod localized from neutron noise measurements in pressurized water reactors (PWRs). The neutron noise can also be used to measure the moderator temperature coefficient of reactivity (MTC), the stability of boiling water reactors (BWRs), and in general for detecting any anomaly at an early stage through the change of the neutron noise spectra.

The process of neutron noise diagnostics consists of first constructing a simple model of the noise source under investigation, which contains only a few parameters to be determined, calculating the induced noise through calculating the dynamic transfer function of the system, and constructing an inversion procedure by which, from the measurements of the neutron noise, one can unfold the searched parameters of the noise source (perturbation). The underlying theory and methods will be expounded in the forthcoming sections. For more details, we can refer the reader to a few monographs, conference proceedings, and review articles, such as Williams (1974), Saito (1979), Kosály (1980), and Thie (1981). Another useful source of information is the proceedings of the eight SMORN symposia held so far in the field, several of which were published in *Progress in Nuclear Energy*. These can be found at the OECD NEA Web site (OECD 2002).

3.1 Basic Principles

Starting with a critical reactor with time-independent cross sections, any change of the cross sections will lead to changes of the neutron flux in space and time. These changes will occur irrespective of the change of the cross sections is a random process or a deterministic one, but their character (deterministic or not) will match the change of the cross sections (perturbations). A

large class of the changes consists of small variations of the cross sections around an expected value, corresponding to the critical case, in which the perturbation can be called a noise source, and the induced flux fluctuations the neutron noise.

The neutron noise $\delta\phi(\mathbf{r}, t)$ is hence defined through

$$\delta\phi(\mathbf{r}, t) \equiv \phi(\mathbf{r}, t) - \langle \phi(\mathbf{r}, t) \rangle = \phi(\mathbf{r}, t) - \phi_0(\mathbf{r}), \quad (126)$$

with $\phi_0(\mathbf{r})$ being the static flux, and the noise source $\delta\Sigma(\mathbf{r}, t)$ through the fluctuation of the macroscopic cross sections (perturbations) as

$$\delta\Sigma(\mathbf{r}, t) \equiv \Sigma(\mathbf{r}, t) - \langle \Sigma(\mathbf{r}, t) \rangle \quad (127)$$

One would think that these flux fluctuations could also be described by the master equation technique, that is, through the setting up of a probability balance equation for the distribution of the neutrons in space and time. Such a description is possible in principle, but it is associated with severe problems, both conceptual and practical (Pázsit et al. 2002; Pál and Pázsit 2006, 2007). The conceptual ones concern the fact that the master equation approach is based on the transition intensities between the different states of the system, which in the case of neutron chains are related to the nuclear cross sections. In the case of zero power systems, these are constant. In the case of power reactor noise, the cross sections, that is, the transition probabilities, become random processes themselves. Hence, the neutron transport and multiplication in a temporally varying system becomes a “doubly stochastic process.” Such a process can only be formulated for a temporally varying homogeneous medium with two discrete states, which is a poor approximation of the real case.

Such an approach was discussed recently, as is described in Pázsit and Pál (2008). It was shown that even in the case of a homogeneous system with a homogeneous perturbation in the form of a dichotomic Markov process, the solution is rather involved. Solutions for more realistic cases, involving space-dependence and continuous variations of the system properties, are in practice impossible. On the other hand, the case of spatially constant perturbations is completely uninteresting from the point of view of power reactor noise diagnostic problems.

There is one further subtle point to this. Because the changes of the system affect all neutrons in the system over the volume of the perturbation, the neutron chains started in a branching process (fission) will not be independent. Hence the factorization property, based on the independence of the chains, which is a prerequisite for the application of the backward master equation as in (24) and (29)–(31), cannot be applied. Thus, in the case of a temporally varying system, only the forward approach is applicable, which is less powerful than the backward approach.

Hence, in practice, in the theory of power reactor noise another approach is selected. One starts with the space- and time-dependent transport or diffusion equations for the mean (expected) neutron flux. In this equation, the critical (steady-state) cross sections occur as multiplying coefficients. Then, one assumes that there occur fluctuations in some cross sections, corresponding to some ordinary (e.g., boiling) or anomalous (excessive vibrations) process. The fluctuating cross sections are treated as stochastic processes, which are usually described by their autocorrelations and auto-spectra (c.f. (131)–(136)). Because some coefficients of the diffusion equation are now stochastic processes, the equation becomes a stochastic differential equation. Instead of obtaining an explicit solution for $\delta\phi(\mathbf{r}, t)$, its statistical properties (correlations, spectra) can be determined to the same extent as those are known for $\delta\Sigma(\mathbf{r}, t)$. This way, the probability distribution of the noise is not searched, only certain moments. The main

purpose of power reactor noise theory is to find relationships between the statistical properties of the noise source and the induced noise by the solution of the diffusion equation.

It is clear from the above that in the above description of power reactor noise, also called the Langevin technique, the zero power noise (fluctuations inherent in the branching process) is neglected. This is justified because in high-power systems the zero power noise is negligible (its variance is a linear function of the power, whereas the variance of power reactor noise is proportional to the square of the reactor power). Moreover, power reactor noise is indeed generated only in reactors at high power, since the perturbations inducing the noise (boiling, flow-induced vibrations) do not exist in low-power systems and critical assemblies. Hence, for all practical cases, the treatment of power reactor noise through the Langevin technique is fully adequate.

An important fact is that the perturbations (cross section fluctuations) are usually small enough such that the equations can be linearized. This means that the induced noise can be represented as a convolution over the noise source and a system transfer function where the latter is determined by the unperturbed system, that is, it is independent from the properties of the noise source.

The first step of noise diagnostics is to set up a framework for the calculation of the neutron noise for a specified perturbation type. According to the fact mentioned above, an equation for the neutron noise can conceptually be written as

$$\tilde{\mathbf{L}}(\mathbf{r}, t) \delta\phi(\mathbf{r}, t) = S(\mathbf{r}, t) \quad (128)$$

Here, the operator $\tilde{\mathbf{L}}(\mathbf{r}, t)$ is usually the diffusion theory representation of the transport operator, whereas, as it will be shown soon, the perturbation $S(\mathbf{r}, t)$ is simply related to the fluctuations of the cross sections as

$$S(\mathbf{r}, t) = \delta\Sigma(\mathbf{r}, t)\phi_0(\mathbf{r}). \quad (129)$$

This equation is sometimes called a Langevin equation, at least when the right-hand side is a white noise (a Wiener process). A white noise is a process whose correlation function is a Dirac-delta function and thus its power spectrum is a constant.

In (129), the perturbation $S(\mathbf{r}, t)$, also called the driving force, or rather the cross section fluctuation $\delta\Sigma(\mathbf{r}, t)$ cannot be specified explicitly, only its correlation function or spectrum is known (or the correlations or spectra of its individual parameters). All processes will be assumed stationary and ergodic. Thus, the mean value of the perturbation is time-independent and identically zero:

$$\langle \delta\Sigma(\mathbf{r}, t) \rangle = 0. \quad (130)$$

Its correlation function is given as

$$CCF_{\Sigma}(\mathbf{r}, \mathbf{r}', \tau) = \langle \delta\Sigma(\mathbf{r}, t) \delta\Sigma(\mathbf{r}', t + \tau) \rangle = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T \delta\Sigma(\mathbf{r}, t) \delta\Sigma(\mathbf{r}', t + \tau) dt \quad (131)$$

The above quantity is called a cross-correlation because it describes correlations between different spatial points. The cross-spectrum is the Fourier transform of the correlation function

$$CPSD_{\Sigma}(\mathbf{r}, \mathbf{r}', \omega) = \int_{-\infty}^{\infty} CCF_{\Sigma}(\mathbf{r}, \mathbf{r}', \tau) e^{-i\omega\tau} d\tau \quad (132)$$

Usually this is all one can specify about the perturbation. The goal is to calculate the auto- and cross-spectra of the induced noise from this information and (128). That is, one wants to know

$$CCF_{\phi}(\mathbf{r}, \mathbf{r}', \tau) = \langle \delta\phi(\mathbf{r}, t) \delta\phi(\mathbf{r}', t + \tau) \rangle = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T \delta\phi(\mathbf{r}, t) \delta\phi(\mathbf{r}', t + \tau) dt \quad (133)$$

and

$$CPSD_{\phi}(\mathbf{r}, \mathbf{r}', \omega) = \int_{-\infty}^{\infty} CCF_{\phi}(\mathbf{r}, \mathbf{r}', \tau) e^{-i\omega\tau} d\tau \quad (134)$$

In practical work, the power spectra are often calculated by the Wiener–Khinchin theorem, which states that for ergodic processes

$$CPSD_{\Sigma}(\mathbf{r}, \mathbf{r}', \omega) \propto \delta\Sigma(\mathbf{r}, \omega) \delta\Sigma^*(\mathbf{r}', \omega) \quad (135)$$

and hence

$$CPSD_S(\mathbf{r}, \mathbf{r}', \omega) \propto S(\mathbf{r}, \omega) S^*(\mathbf{r}', \omega) \quad (136)$$

The above relationship is useful when the auto- and cross-spectra of the noise are searched as functions of the auto- and cross-spectra of the perturbation. To find such a relationship it is sufficient to find the solution of the Fourier transformed diffusion equations. This means that if one finds the noise in the form

$$\delta\phi(\mathbf{r}, \omega) = \int G(\mathbf{r}, \mathbf{r}', \omega) S(\mathbf{r}', \omega) d\mathbf{r}', \quad (137)$$

where the noise source $S(\mathbf{r}, \omega)$ is given, as will be seen later, as

$$S(\mathbf{r}, \omega) = \phi_0(\mathbf{r}) \delta\Sigma(\mathbf{r}, \omega) \quad (138)$$

with $\phi_0(\mathbf{r})$ being the static neutron flux, then, through (135), one has

$$CPSD_{\phi}(\mathbf{r}, \mathbf{r}', \omega) = \int G(\mathbf{r}, \mathbf{r}_1, \omega) G^*(\mathbf{r}', \mathbf{r}_1', \omega) CPSD_S(\mathbf{r}_1, \mathbf{r}_1', \omega) d\mathbf{r}_1 d\mathbf{r}_1' \quad (139)$$

The transfer function or Green's function $G(\mathbf{r}, \mathbf{r}', \omega)$ can be determined from (128) as it will be shown concretely below.

The purpose of power reactor noise studies is to find relationships between noise source and induced noise in the form of (138). In conceptual studies, rather (137) is used, because it is more

transparent. The various forms of noise diagnostics can then be illustrated as follows. In (137), there are three quantities:

1. The induced neutron noise, $\delta\phi(\mathbf{r}, \omega)$, which is always measured;
2. The dynamic transfer function $G(\mathbf{r}, \mathbf{r}', \omega)$, which can be calculated from the time- (frequency-) dependent diffusion equations with the parameters of the unperturbed system;
3. The noise source $S(\mathbf{r}, \omega)$.

If two of these three are known, the third can be determined, in principle. The generic task is that the transfer function is known from calculations, and the noise source is unknown. The objective is to invert (137) to express the noise source with the transfer function and the measured noise.

Mathematically, (137) is a Fredholm-type integral equation which, under some mild circumstances, can be uniquely inverted. However, this requires that the functions $\phi_0(\mathbf{r})$ and $G(\mathbf{r}, \mathbf{r}', \omega)$ are known everywhere in the reactor as continuous functions of their parameters. While this is true for the transfer function, which is determined by calculations, the same is not true for the detected noise. The noise is only measured in the discrete positions of the neutron detectors, which are actually placed quite sparse in the reactor. This means that for arbitrary perturbations $S(\mathbf{r}, \omega)$, the inversion is not possible.

This is where noise diagnostics expertise is invoked to solve this problem. Namely, in most cases of perturbations to be diagnosed, such as a vibrating control rod, two-phase flow in a channel, etc., one can make a simple model of the perturbation in form of a mathematical function, which only contains a few unknown parameters (position of a control rod, void fraction fluctuation, etc). Examples will be given soon. Those few parameters can be determined from the signals of a few neutron detectors.

Another way of performing diagnostics is to determine some parameter of the transfer function. As earlier mentioned, the functional form of the transfer function can always be calculated from the neutron kinetic (diffusion) equations, if all the parameters (cross sections, delayed neutron data, reactivity in case of subcritical systems, etc.) are known. Sometimes certain parameters are not known, and the diagnostics is aimed at determining those parameters. In that case, one needs to measure both the perturbation (e.g., inlet temperature fluctuations) and the induced neutron noise, to determine for example, reactivity coefficients, such as the moderator temperature coefficient. If some assumptions can be made on the driving force, such as in the case of BWR instability, the stability of the system can be determined solely from the measured neutron noise.

3.2 Space-Time Dependent Reactor Kinetics in Diffusion Theory

A suitable starting point is to study the space-time dynamic response of a reactor to perturbations in the deterministic case, and to define some concepts, notably the reactor kinetic approximations, out of which the two lowest order (point kinetic and adiabatic) will come to use in the interpretation of the behavior of the system. The stochastic nature of the perturbations will be considered in the next subsection, treating small perturbations where linear theory is applicable and the effect of the noise source and the system transfer properties factorize.

All derivations will be made in one- or two-group diffusion theory. This level of the description was chosen because it has proven completely satisfactory so far in all known cases of practical interest. In a few cases such as the treatment of voids the use of P_1 theory might be

called for (Kleiss and van Dam 1978), but the general conclusion is that in most cases diffusion theory is fully sufficient (Pázsit 2002; Larsson and Demazière 2009). The number of the energy groups used is dictated by the nature of the perturbation and the diagnostic task considered. In one-group diffusion theory, the characteristic equation, both in the static case and the dynamic case, has only one root, and hence one large spatial relaxation length, on the scale of the migration distance. This solution will be able to describe only the global behavior of the system. This global behavior is point kinetic in small systems and/or low frequencies, but deviates from it, still on a relatively large spatial scale, in larger systems and/or higher frequencies. In this case, we speak about space-dependent noise, and the deviation from the point-kinetic behavior is called “the space-dependent term” of the response. In most cases, this space-dependence of the behavior, as calculated in one-group theory, is sufficient to solve the diagnostic problem, because the spacing of the detectors and the distance of the detectors to the noise source is on the same scale as the relaxation length. However, as mentioned earlier, in the neighborhood of a localized perturbation there exists also a third component with a short spatial relaxation length, comparable with the thermal diffusion length in the system. This is called the local component of the noise. In order to obtain the local component, one needs to use two energy groups, since the characteristic equation in two-group theory has two roots, giving two spatial relaxation lengths. The longer one is approximately the same as the one obtained from one-group theory. The shorter one describes, in the static case, the reflector peak and the local flux dip around control rods. In cases when the detectors are close to the perturbation, such as in the case of BWR in-core detectors sensing the effect of bubbles passing by, one has to account for the local component, and hence has to use two-group theory.

For the transparency of the description, the emphasis of the description will be on one-group theory in the forthcoming sections. Basic features of the two-group description will be mentioned when necessary, but with the details of derivations we will refer to the literature.

3.2.1 Static Equations

One-Group Theory

With obvious notations, the static equation reads as

$$\nabla D(\mathbf{r}) \nabla \phi_0(\mathbf{r}) + [\nu \Sigma_f(\mathbf{r}) - \Sigma_a(\mathbf{r})] \phi_0(\mathbf{r}) = 0 \quad (140)$$

with the boundary conditions of vanishing flux at the system boundaries, that is,

$$\phi_0(\mathbf{r}_B) = 0 \quad (141)$$

where $\mathbf{r}_B$ is an arbitrary point on the extrapolated boundary. Usually, we will assume a homogeneous, or piecewise homogeneous system, in which case (140) is simplified to

$$D \nabla^2 \phi_0(\mathbf{r}) + [\nu \Sigma_f - \Sigma_a] \phi_0(\mathbf{r}) = 0 \quad (142)$$

Introducing the material buckling

$$B_m^2 = \frac{\nu \Sigma_f - \Sigma_a}{D} \quad (143)$$

the equation is further simplified to

$$\nabla^2 \phi_0(\mathbf{r}) + B_m^2 \phi_0(\mathbf{r}) = 0 \quad (144)$$

The criticality equation is obtained by noticing that only specific values of the material buckling are allowed, which fulfill the boundary condition (141). These values depend on the system geometry, and are denoted by B_g^2 . The criticality equation can be symbolically written as $B_g^2 = B_m^2 \equiv B_0^2$. A system that we will frequently use for illustration is a homogeneous one-dimensional non-reflected reactor with extrapolated boundaries at $x_B = \pm a$. In that case, the critical flux is given as

$$\phi_0(x) = A \cos(B_0 x) \quad (145)$$

with $B_0 = \pi/2a$, and the criticality equation reads as

$$\frac{\nu \Sigma_f - \Sigma_a}{D} = \left(\frac{\pi}{2a} \right)^2 \quad (146)$$

Because of its practical and methodological importance, we shall also treat a nonhomogeneous case by assuming that the system contains a thin absorber rod. As a mathematical simplification, this rod will be described by an absorption cross section, which is a spatial Dirac-delta function. That is, we assume

$$\Sigma_a^{rod}(x) = \gamma \delta(x - x_p) \quad (147)$$

where x_p is the position of the rod, and γ is the so-called Galanin factor, describing the strength of the rod. The static equation for this case reads as

$$D \nabla^2 \phi_0(x) + (\nu \Sigma_f - \Sigma_a) \phi_0(x) - \gamma \delta(x - x_p) \phi_0(x) = 0 \quad (148)$$

Noting that for $x \neq x_p$ the above equation is the same as (144), the solution can be obtained easily in the two half-spaces separated by the rod. Continuity of the flux at $x = x_p$ and the discontinuity of the current, obtained by integrating (148) between $x_p - \varepsilon$ and $x_p + \varepsilon$, leading to

$$\left. \frac{d\phi_0(x)}{dx} \right|_{x_p + \varepsilon} - \left. \frac{d\phi_0(x)}{dx} \right|_{x_p - \varepsilon} = \frac{\gamma}{D} \phi_0(x_p)$$

that leads to the solution

$$\phi_0(x) = A \begin{cases} \sin B_0(a + x) \sin B_0(a - x_p) & x \leq x_p \\ \sin B_0(a - x) \sin B_0(a + x_p) & x \geq x_p \end{cases} \quad (149)$$

where A is an arbitrary constant, and to the criticality equation

$$\cot B_0(x_p - a) - \cot B_0(x_p + a) = \frac{\gamma}{B_0 D} \quad (150)$$

The solution (149), with material and geometrical data corresponding to a light water power reactor, is shown in  Fig. 6.

■ Figure 6

Static neutron flux in one-group diffusion theory for a bare homogeneous reactor with a thin absorber rod located at $x_p = -30$ cm and a Galanin constant $\gamma = 0.01$

As seen from the figure, the presence of the control rod causes a global change of the flux shape compared to the pure cosine shape without the rod. The local flux dip is not reconstructed by the one-group treatment.

Two-Group Theory

The two-group static equations can be most conveniently written in a matrix notation. For simplicity, a homogeneous system will be assumed only. The equations for the fast and thermal fluxes $\phi_1(\mathbf{r})$ and $\phi_2(\mathbf{r})$, respectively, read as

$$\begin{bmatrix} D_1 \nabla^2 + \nu \Sigma_{f_1} - \Sigma_{a_1} - \Sigma_R & \nu \Sigma_{f_2} \\ \Sigma_R & D_2 \nabla^2 - \Sigma_{a_2} \end{bmatrix} \begin{bmatrix} \phi_1(\mathbf{r}) \\ \phi_2(\mathbf{r}) \end{bmatrix} = 0 \quad (151)$$

Here, subscripts 1 and 2 refer to the fast and the thermal flux, respectively, and Σ_R is the removal cross section.

It is easy to show that both the fast flux and the thermal flux have to obey the same Helmholtz equation

$$\nabla^2 \phi_g(\mathbf{r}) + B^2 \phi_g(\mathbf{r}) = 0; \quad g = 1, 2 \quad (152)$$

where B^2 denotes any of the two roots μ^2 and ν^2 of the characteristic equation, second order in B^2 :

$$\begin{vmatrix} -D_1 B^2 + \nu \Sigma_{f_1} - \Sigma_{a_1} - \Sigma_R & \nu \Sigma_{f_2} \\ \Sigma_R & -D_2 B^2 - \Sigma_{a_2} \end{vmatrix} = 0 \quad (153)$$

The solution of this equation in one dimension can be written as

$$\begin{pmatrix} \phi_1(x) \\ \phi_2(x) \end{pmatrix} = A \begin{pmatrix} 1 \\ c_\mu \end{pmatrix} \cos \mu x + C \begin{pmatrix} 1 \\ c_\nu \end{pmatrix} \cosh \nu x \quad (154)$$

with

$$c_\mu = \frac{\Sigma_R}{D_2 \mu^2 + \Sigma_{a_2}} \quad \text{and} \quad c_\nu = \frac{\Sigma_R}{\Sigma_{a_2} - D_2 \nu^2} \quad (155)$$

With the data of light water reactors, $\nu \gg \mu$, and correspondingly the first term in (154) describes a smoothly varying term (global term) whereas the second represents a fast decaying local term. The second term is associated with the reflector peak in the thermal flux in a reflected reactor, and it describes the local flux dip around a thin control rod. In a bare homogeneous system, only the first, slowly varying term exists.

3.2.2 Time-Dependent One-Group Diffusion Equations

When describing the temporal variations, we need to account for the presence of the delayed neutrons. Similar to the case of zero power noise, most characteristics of the dynamical response of the core can be satisfactorily described by one, average group of delayed neutrons with decay constant λ and density of delayed neutron precursors $C(\mathbf{r}, t)$. The coupled equations for the neutron flux and the precursor density read as

$$\frac{1}{\nu} \frac{\partial \phi(\mathbf{r}, t)}{\partial t} = D \nabla^2 \phi(\mathbf{r}, t) + [\nu \Sigma_f(\mathbf{r}, t)(1 - \beta) - \Sigma_a(\mathbf{r}, t)] \phi(\mathbf{r}, t) + \lambda C(\mathbf{r}, t) \quad (156)$$

$$\frac{\partial C(\mathbf{r}, t)}{\partial t} = \beta \nu \Sigma_f(\mathbf{r}, t) \phi(\mathbf{r}, t) - \lambda C(\mathbf{r}, t) \quad (157)$$

Here, for simplicity and according to general praxis, the fluctuations of the diffusion coefficient were disregarded. The second equation can easily be integrated and substituted back to the first, leading to the integrodifferential form

$$\begin{aligned} \frac{1}{\nu} \frac{\partial \phi(\mathbf{r}, t)}{\partial t} = & D \nabla^2 \phi(\mathbf{r}, t) + [\nu \Sigma_f(\mathbf{r}, t)(1 - \beta) - \Sigma_a(\mathbf{r}, t)] \phi(\mathbf{r}, t) \\ & + \lambda \beta \int_{-\infty}^t \nu \Sigma_f(\mathbf{r}, t') \phi(\mathbf{r}, t') e^{-\lambda(t-t')} dt' \end{aligned} \quad (158)$$

Equations (156) and (157), or (158) are difficult to solve for arbitrary variations of the cross sections analytically, and in the early days it was difficult even numerically. Historically, the so-called reactor kinetics approximations were introduced via the flux factorization technique of Henry (1958, 1975) in order to obtain numerical solutions. The role of the kinetic approximations as a tool for numerical analysis has long been diminished, but their value remains for the interpretation and for solving diagnostic tasks. Therefore, a brief survey will be given here.

3.2.3 The Flux Factorization and the Kinetic Approximations

The basis of the kinetic approximations after Henry (1958, 1975) is a factorization of the space-time dependent flux into an amplitude factor $P(t)$ and a normalized shape function $\psi(\mathbf{r}, t)$ as

$$\phi(\mathbf{r}, t) = P(t)\psi(\mathbf{r}, t) \quad (159)$$

To make the factorization unique, an extra condition is needed. Such a condition will be formulated with the intention to collect all changes of the total reactor power, or the total neutron number in the system, into the amplitude function, and to have the shape function to describe the shape changes of the flux in a normalized manner. In the general space-energy-angularly dependent case, this is specified as

$$\frac{\partial}{\partial t} \int \phi_0^\dagger(\mathbf{r}, E, \Omega) \psi(\mathbf{r}, E, \Omega t) d\mathbf{r} dE d\Omega = 0 \quad (160)$$

where $\phi_0^\dagger(\mathbf{r}, E, \Omega)$ is the static adjoint of the reference critical system (Bell and Glasstone, 1970). In two-group diffusion theory, the angular variable and the corresponding integral are omitted, and the integral with respect to the energy variable is replaced by a summation over the energy groups. In one-group diffusion theory, which is the case that we will be concerned with in the continuation, the situation is even simpler since also the energy variable is missing, and the static flux can be used instead of the static adjoint, since one-group diffusion theory is self-adjoint. Hence, the normalization condition becomes

$$\frac{\partial}{\partial t} \int \phi_0(\mathbf{r}) \psi(\mathbf{r}, t) d\mathbf{r} = 0 \quad (161)$$

with

$$\phi_0(\mathbf{r}) = P_0 \psi(\mathbf{r}, t = 0) \quad (162)$$

That is, it is assumed that at time $t = 0$ the system was in an unperturbed critical state with a static flux $\phi_0(\mathbf{r})$, obeying (140). Actually in (162) there is still a freedom to choose either P_0 , or the amplitude of the shape function at $t = 0$ (or at $t = -\infty$, which is the usual procedure in noise analysis where the processes are stationary and the transient effects of the “switching on” the perturbation are of no interest) arbitrarily. In the analysis of large reactivity excursions and other transients, P_0 is chosen to be equal to the thermal power generated in the core. In noise analysis work, found frequently in the literature, it is customary to use $P_0 = 1$, which yields $\psi(\mathbf{r}, t = 0) = \phi_0(\mathbf{r})$.

With the above assumptions one can derive coupled equations for the amplitude function and the shape function. Multiplying (140) by $P(t)\psi(\mathbf{r}, t)$ and (156) and (157) by $\phi_0(\mathbf{r})$, integrating and subtracting the static equation from the dynamic ones leads to two coupled equations for the amplitude function, known as the point-kinetic equations:

$$\frac{dP(t)}{dt} = \frac{\rho(t) - \beta}{\Lambda(t)} P(t) + \lambda C(t) \quad (163)$$

and

$$\frac{dC(t)}{dt} = \frac{\beta}{\Lambda(t)} P(t) - \lambda C(t) \quad (164)$$

Here,

$$\rho(t) = \frac{1}{F(t)} \int \{ \delta v \Sigma_f(\mathbf{r}, t) - \delta \Sigma_a(\mathbf{r}, t) \} \phi_0(\mathbf{r}) \psi(\mathbf{r}, t) d\mathbf{r}, \quad (165)$$

$$\Lambda(t) = \frac{1}{F(t)} \int \frac{1}{v} \phi_0(\mathbf{r}) \psi(\mathbf{r}, t) d\mathbf{r} \quad (166)$$

and

$$C(t) = \frac{1}{\Lambda(t)F(t)} \int C(\mathbf{r}, t) \phi_0(\mathbf{r}) d\mathbf{r} \quad (167)$$

with

$$F(t) = \int v \Sigma_f(\mathbf{r}, t) \phi_0(\mathbf{r}) \psi(\mathbf{r}, t) d\mathbf{r} \quad (168)$$

The fluctuations of the cross sections are defined as

$$\delta v \Sigma_f(\mathbf{r}, t) = v \Sigma_f(\mathbf{r}, t) - v \Sigma_f(\mathbf{r}) \quad \text{and} \quad \delta \Sigma_a(\mathbf{r}, t) = \Sigma_a(\mathbf{r}, t) - \Sigma_a(\mathbf{r}) \quad (169)$$

The point-kinetic equations (163) and (164) can be readily solved if the parameters $\rho(t)$ and $\Lambda(t)$ are known. The calculation of these latter requires knowledge of the shape function $\psi(\mathbf{r}, t)$, which obeys a complicated equation. The various reactor kinetic approximations consist of an approximate calculation of the shape function. In linear noise theory, valid for small perturbations, these parameters will be constants, and independent of the shape function.

An equation for the shape function can be obtained by putting $P(t)\psi(\mathbf{r}, t)$ into (158), which will read as

$$\begin{aligned} \frac{1}{v} \left[\frac{\partial \psi(\mathbf{r}, t)}{\partial t} + \frac{1}{P(t)} \frac{dP(t)}{dt} \psi(\mathbf{r}, t) \right] &= D \nabla^2 \psi(\mathbf{r}, t) + [v \Sigma_f(\mathbf{r}, t)(1 - \beta) - \Sigma_a(\mathbf{r}, t)] \psi(\mathbf{r}, t) \\ &\quad + \frac{Q_d(\mathbf{r}, t)}{P(t)} \end{aligned} \quad (170)$$

where $Q_d(\mathbf{r}, t)$ is the “delayed neutron source,” given as

$$Q_d(\mathbf{r}, t) = \lambda \beta \int_{-\infty}^t v \Sigma_f(\mathbf{r}, t') P(t') \psi(\mathbf{r}, t') e^{-\lambda(t-t')} dt' \quad (171)$$

This equation is considerably more difficult to solve than the original diffusion equation (158) for the full solution, partly because it contains the other unknown, the amplitude function. Thus, in order to make the flux factorization useful, one needs to use simplifications in its calculation. We shall only discuss the two lowest-order approximations, the point reactor approximation, and the adiabatic approximation.

The Point Reactor Approximation

Here it is assumed that the shape function at any time is equal to the time-independent static flux, that is,

$$\psi(\mathbf{r}, t) = \phi_0(\mathbf{r}), \quad \forall t \quad (172)$$

Then the parameters ρ and Λ are constants, and the point-kinetic equations can be readily solved for $P(t)$. The space-time dependent flux is thus given as

$$\phi(\mathbf{r}, t) = P(t)\phi_0(\mathbf{r}) \quad (173)$$

This description is suitable for large power excursions or any other changes where the shape function does not change appreciably during the process. If the reactor behavior can be described by this approximation, then only the information of the time-dependence of the flux can be used to extract information on the perturbation causing the flux change, because the spatial dependence of the flux is independent from that of the perturbation.

The Adiabatic Approximation

A somewhat more effective approximation, in which the shape function has a time-varying space-dependence, but where the equations for the amplitude function and shape function still fully decouple is the adiabatic approximation. In this approximation the shape function at each time instant is assumed to be equal to the normalized (in the sense of (161) and (162)) k -eigenvalue equation of the system, belonging to the momentary values of $v\Sigma_f(\mathbf{r}, t)$ and $\Sigma_a(\mathbf{r}, t)$:

$$D\nabla^2\psi(\mathbf{r}, t) + \left[\frac{v\Sigma_f(\mathbf{r}, t)}{k(t)} - \Sigma_a(\mathbf{r}, t) \right] \psi(\mathbf{r}, t) = 0 \quad (174)$$

Here, the time t is only a parameter, and not a variable, and the equation is a static one. Formally, this equation can be obtained from (170) by neglecting all time derivatives and assuming that the delayed neutron source (171) is a constant. Obviously no dynamics is involved, and it is assumed that both the flux *and* the delayed precursor distribution correspond to an equilibrium distribution. This approximation can be used only for slow changes and preferably for small perturbations, but it is a very effective tool for interpreting the results of noise calculations and in order to devise noise unfolding techniques.

A better approximation, which takes into account that the prompt neutron distribution can readjust to the changed cross sections, while the delayed neutron precursors cannot, is the quasistatic approximation. In this approximation, only the time derivative of the shape function, the first term on the left-hand side of (170), is neglected. Further, in this approximation, the equations for the amplitude function and for the shape function remain coupled, and the solution of the latter is rather complicated. The efficiency of the method as compared to solve the original equations (156) and (157) is that in the numerical solution of the shape function a much larger time step can be used than in the solution of the much simpler ordinary differential equations (163) and (164). On the other hand, the solution of the quasistatic approximation cannot be interpreted in such easy intuitive terms as that of the adiabatic approximation.

3.3 Small Space-Time Dependent Fluctuations: Power Reactor Noise

In power reactor noise theory one concerns with perturbations represented by small, stationary fluctuations of the cross sections about their expectation (mean value). The static values (the expectations) are supposed to constitute a critical reactor. The perturbation is supposed to start at $t = -\infty$, so that all transients have already decayed by finite times, and temporal Fourier transform can be used to solve time-dependent equations. The task of noise theory is to calculate

the space-time (or rather, space-frequency) dependence of the fluctuations of the neutron flux around its static value, and this will be described in this subsection. The task of noise diagnostics is to invert the obtained solutions, which will be described in the following subsections.

3.3.1 Neutron Noise in One-Group Diffusion Theory

The equations giving the time- and space-dependent neutron flux in diffusion theory in ► Subsect. 3.2.2, (156) and (157), were derived in the general case. Now some assumptions will be made in order to estimate the neutron noise in first-order linear theory.

Splitting all the time-dependent terms, generically expressed as $X(\mathbf{r}, t)$, into their mean values $X_0(\mathbf{r})$ (corresponding to the steady state and thus critical configuration of the system) and their fluctuations $\delta X(\mathbf{r}, t)$ around their mean values as

$$X(\mathbf{r}, t) = X_0(\mathbf{r}) + \delta X(\mathbf{r}, t) \quad (175)$$

where X stands for the macroscopic cross sections Σ_α of type α , the concentration C of the delayed neutron precursors, and the neutron flux ϕ , the following assumptions can be made:

- The fluctuations are assumed to be small compared to the mean values, that is,

$$|\delta X(\mathbf{r}, t)| \ll X_0(\mathbf{r}), \quad \forall (\mathbf{r}, t) \quad (176)$$

such that the product of any two fluctuating quantities can be neglected, and

- The processes are assumed to be stationary, that is,

$$\langle \delta X(\mathbf{r}, t) \rangle = 0, \quad \forall (\mathbf{r}, t) \quad (177)$$

which results in

$$\langle X(\mathbf{r}, t) \rangle = X_0(\mathbf{r}), \quad \forall (\mathbf{r}, t) \quad (178)$$

With these assumptions, the fluctuations $\langle \delta X(\mathbf{r}, t) \rangle$ are defined as the first-order noise. The extension of these assumptions for two-group theory is straightforward.

Substituting the generic expression given by (175) for all time-dependent parameters in (156)–(157), the second-order terms (i.e., terms of the form $\delta X(\mathbf{r}, t) \cdot \delta Y(\mathbf{r}, t)$) can be neglected because of the assumed smallness of the fluctuations. Subtracting the time-independent equation (140) and performing a Fourier transform leads to

$$\begin{aligned} \nabla \cdot D(\mathbf{r}) \nabla \delta \phi(\mathbf{r}, \omega) + \left\{ \left[1 - \frac{i\omega\beta}{i\omega + \lambda} \right] v \Sigma_f(\mathbf{r}) - \Sigma_a(\mathbf{r}) - \frac{i\omega}{v} \right\} \delta \phi(\mathbf{r}, \omega) \\ = \left\{ \delta \Sigma_\alpha(\mathbf{r}, \omega) - \left[1 - \frac{i\omega\beta}{i\omega + \lambda} \right] \delta v \Sigma_f(\mathbf{r}, \omega) \right\} \phi_0(\mathbf{r}) \end{aligned} \quad (179)$$

where the temporal Fourier transform of any quantity $\delta X(\mathbf{r}, t)$ is estimated as

$$\delta X(\mathbf{r}, \omega) = \int_{-\infty}^{\infty} \exp(-i\omega t) \delta X(\mathbf{r}, t) dt \quad (180)$$

Compared to the static equation (140), it can be noticed that the equation for the neutron noise is an inhomogeneous equation, whereas the equation for the static flux is a homogeneous one. From this viewpoint, the equation for the neutron noise is easier to solve, although the quantities in (179) are complex quantities.

With introducing some notations usual in reactor dynamics and neutron noise theory, (179) can be written in the simpler form

$$\Delta \delta \phi(\mathbf{r}, \omega) + B^2(\omega) \cdot \delta \phi(\mathbf{r}, \omega) = \frac{S(\mathbf{r}, \omega)}{D} \quad (181)$$

with

$$B^2(\omega) = B_0^2 \left(1 - \frac{1}{\rho_\infty \cdot G_0(\omega)} \right) \quad (182)$$

where $G_0(\omega)$ is the “zero-power reactor transfer function” defined as

$$G_0(\omega) = \frac{1}{i\omega \left(\Lambda + \frac{\beta}{i\omega + \lambda} \right)} \quad (183)$$

and further,

$$\rho_\infty = 1 - \frac{1}{k_\infty} = 1 - \frac{\Sigma_a}{\nu \Sigma_f} \quad (184)$$

and

$$S(\mathbf{r}, \omega) = \left\{ \delta \Sigma_a(\mathbf{r}, \omega) - \left[1 - \frac{i\omega \beta}{i\omega + \lambda} \right] \delta \nu \Sigma_f(\mathbf{r}, \omega) \right\} \phi_0(\mathbf{r}) \quad (185)$$

The Green's function of (181) will be calculated later on.

3.3.2 The Factorization of the Neutron Noise

We shall derive the neutron noise in the so-called point-kinetic approximation, which has been often used when evaluating measurements, especially at the early days of power reactor noise. As a starting point, the equations giving the fluctuations of the amplitude factor and of the shape functions are derived in linear theory.

As described earlier, the reactor physics approximations are based on the factorization of the time- and space-dependent neutron flux into an amplitude factor and a shape function as

$$\phi(\mathbf{r}, t) = P(t) \cdot \psi(\mathbf{r}, t) \quad (186)$$

Splitting the time-dependent parameters to mean values and fluctuations according to (175) results in

$$P(t) = P_0 + \delta P(t) \quad (187)$$

$$\psi(\mathbf{r}, t) = \psi(\mathbf{r}, t = 0) + \delta \psi(\mathbf{r}, t) \quad (188)$$

$$\phi(\mathbf{r}, t) = \phi_0(\mathbf{r}) + \delta \phi(\mathbf{r}, t) \quad (189)$$

Due to (162), (188) leads to

$$\psi(\mathbf{r}, t) = \frac{\phi_0(\mathbf{r})}{P_0} + \delta\psi(\mathbf{r}, t) \quad (190)$$

Using (187) and (190) in (189) and neglecting second-order terms gives

$$\delta\phi(\mathbf{r}, t) = \underbrace{\phi_0(\mathbf{r}) \cdot \frac{\delta P(t)}{P_0}}_{\text{point-reactor term}} + \underbrace{P_0 \cdot \delta\psi(\mathbf{r}, t)}_{\text{space-dependent term}} \quad (191)$$

The above composition of the neutron noise from a point reactor term, driven by the reactivity effect of the perturbation, and a space-dependent term, which is driven by the nonuniform (in space) character of the perturbation, is basic in reactor noise theory.

We also see from (161)–(162) that the fluctuation of the shape function, that is, the space-dependent term and the static flux are orthogonal. This reads as

$$\int \phi_0(\mathbf{r}) \delta\psi(\mathbf{r}, t) d\mathbf{r} = 0 \quad (192)$$

Determination of the Fluctuations of the Amplitude Factor

It was shown in ► 5.2.2 that the amplitude factor $P(t)$ fulfills the following time-dependent equations:

$$\frac{dP(t)}{dt} = \frac{\rho(t) - \beta}{\Lambda(t)} P(t) + \lambda C(t) \quad (193)$$

$$\frac{dC(t)}{dt} = \beta \frac{P(t)}{\Lambda(t)} - \lambda C(t) \quad (194)$$

In the static case, these equations result in $\rho_0 = 0$ (critical system).

Noticing that in first-order theory one has $\Lambda(t) = \Lambda, \forall t$ where

$$\Lambda = \frac{1}{\nu \Sigma_f}, \quad (195)$$

splitting all time-dependent parameters into mean values and fluctuating parts according to (175), neglecting second-order terms and performing a temporal Fourier transform lead to

$$\delta P(\omega) = P_0 \cdot G_0(\omega) \cdot \delta\rho(\omega) \quad (196)$$

where $G_0(\omega)$ is the zero-power reactor transfer function defined in (183). The frequency-dependence of the amplitude and phase of this function is shown in ► Fig. 7. As is also seen from this figure, for the “plateau region”

$$\lambda \ll \omega \ll \frac{\beta}{\Lambda_0}, \quad (197)$$

the amplitude is nearly constant and is equal to

$$|G_0(\omega)| \approx \frac{1}{\beta} \quad (198)$$

whereas the phase delay is close to zero within this region.

The fluctuations of the reactivity in (196) are given in first-order approximation as

$$\delta\rho(\omega) = \frac{\int \{ \delta\nu\Sigma_f(\mathbf{r}, \omega) - \delta\Sigma_a(\mathbf{r}, \omega) \} \phi_0^2(\mathbf{r}) d\mathbf{r}}{\delta\Sigma_{f,0}(\mathbf{r}) \phi_0^2(\mathbf{r}) d\mathbf{r}} \quad (199)$$

Figure 7

Gain and phase of the transfer function $G_0(\omega)$

Since the kinetic approximations will not be derived and discussed in two-group theory here, we just give the corresponding expression for the reactivity in two-group diffusion theory, to give some flavor of the formalism:

$$r(\omega) = \frac{1}{F} \int \left\{ \left[\delta v \Sigma_{f,1}(r, \omega) - \delta \Sigma_{a,1}(r, \omega) - \delta \Sigma_r(r, \omega) \right] \varphi_{1,0}^\dagger(r) \varphi_{1,0}(r) \right. \\ \left. + \delta v \Sigma_{f,2}(r, \omega) \varphi_{1,0}^\dagger(r) \varphi_{2,0}(r) - \delta \Sigma_{a,1}(r, \omega) \right. \\ \left. - \delta \Sigma_{a,2}(r, \omega) \varphi_{2,0}^\dagger(r) \varphi_{2,0}(r) \right\} dr \quad (200)$$

with

$$F = \int \left[v \Sigma_{f,1,0}(r) \varphi_{1,0}^\dagger(r) \varphi_{1,0}(r) + v \Sigma_{f,2,0}(r) \varphi_{1,0}^\dagger(r) \varphi_{2,0}(r) \right] dr$$

The reason for the appearance of the fast and thermal static adjoints is due to the fact that, as mentioned earlier, in an energy-dependent theory, the normalization condition attached to the factorization assumption is defined through the static adjoint (see (160)).

The above shows that, since in linear theory one only needs to keep first-order terms in the expression for the reactivity, the static flux (in two-group theory the static fluxes and adjoints) can be used for its calculation, hence the reactivity can be calculated without knowledge of the shape function. This means that the point-kinetic equations for the fluctuation of the amplitude factor decouple from those of the shape function.

Determination of the Fluctuations of the Shape Function

The equation for the shape function is derived from (181). Rewriting (191) in the frequency domain as

$$\delta \phi(\mathbf{r}, \omega) = \phi_0(\mathbf{r}) \cdot \frac{\delta P(\omega)}{P_0} + P_0 \cdot \delta \psi(\mathbf{r}, \omega) \quad (201)$$

and using this expression in (181), after rearrangements one obtains

$$P_0 \Delta \delta \psi(\mathbf{r}, \omega) + P_0 \cdot B^2(\omega) \delta \psi(\mathbf{r}, \omega) = \frac{S(\mathbf{r}, \omega)}{D_0} + \frac{v \Sigma_{f,0}}{D_0} \phi_0(\mathbf{r}) \delta \rho(\omega) \quad (202)$$

As the above shows, also the equation for the shape function decouples from the point-kinetic equations. Hence, in linear theory the shape function can be calculated in a simpler way than in the general case. However, the solution of (202) is not simpler than that of the full equation (181), so in general, the solution of (202) is not sought. The representation of the noise as a sum of the point-kinetic term and the space-dependent term is useful in the first place for the interpretation of the results, and in cases when the shape function is calculated in the adiabatic approximation.

From (201) and (196), one finds that the flux noise is given by

$$\delta \phi(\mathbf{r}, \omega) = \phi_0(\mathbf{r}) G_0(\omega) \delta \rho(\omega) + P_0 \delta \psi(\mathbf{r}, \omega) \quad (203)$$

Full Solution in One-Group Diffusion Theory

The exact or full solution of neutron noise in linear one-group diffusion theory can be conveniently calculated using the so-called Green's function technique. The Green's function in the general case is given by the solution to the following equation:

$$\nabla_r \cdot D(r) \nabla_r G(r, r', \omega) + \left\{ \left[1 - \frac{i\omega\beta}{i\omega + \lambda} \right] \times v\Sigma_f(r) - \Sigma_a(r) - \frac{i\omega}{\nu} \right\} G(r, r', \omega) = \delta(r - r') \quad (204)$$

where the ∇_r operator is taken with respect to the r variable. With the Green's function, the neutron noise is expressed as

$$\delta\phi(r, \omega) = \int G(r, r', \omega) S(r', \omega) dr' \quad (205)$$

In the following, a homogeneous system, in which an analytical solution can be obtained, will be considered. A finite one-dimensional reactor of dimension $2a$ will be used. For this case, one has

$$\Delta_x G(x, x', \omega) + B^2(\omega) G(x, x', \omega) = \frac{\delta(x - x')}{D_0} \quad (206)$$

and

$$\delta\phi(x, \omega) = \int G(x, x', \omega) \cdot S(x', \omega) dx' \quad (207)$$

with

$$S(x', \omega) = \left\{ \delta\Sigma_a(\omega) - \left[1 - \frac{i\omega\beta}{i\omega + \lambda} \right] \times \delta v\Sigma_f(\omega) \right\} \phi_0(x') \quad (208)$$

and where $B^2(\omega)$ was defined in (182).

Equation (206) is an inhomogeneous equation and is of the same type as (148), except that the right-hand side does not contain the searched function and therefore it is an inhomogeneous equation with a unique solution. Using the same technique in the solution, accounting for the continuity of Green's function and the discontinuity of its derivative at $x = x'$, one obtains

$$G(x, x', \omega) = \begin{cases} -\frac{\sin[B(\omega)(a+x)] \cdot \sin[B(\omega)(a-x')]}{D_0 B(\omega) \sin[2B(\omega)a]} & x \leq x' \\ -\frac{\sin[B(\omega)(a-x)] \cdot \sin[B(\omega)(a+x')]}{D_0 B(\omega) \sin[2B(\omega)a]} & x > x' \end{cases} \quad (209)$$

An illustration of the space-dependence of the amplitude (absolute value) of the above Green's function $G(x, x', \omega)$ for a non-central perturbation is shown in ► Fig. 8 with the data of a power reactor.

The neutron noise that can be determined by (206)–(208) corresponds to the neutron noise induced by a localized perturbation at $x = x'$, which changes its strength with a frequency ω . Such a perturbation is sometimes referred to as the neutron noise induced by an “absorber of variable strength” or “reactor oscillator.”

■ Figure 8

Space-dependence of the amplitude of the one-dimensional Green's function $G(x, x', \omega)$ in one-group diffusion theory for $x' = -30$ cm at 1 Hz

Figure 8 shows that in a power reactor and at a frequency of $f = 1$ Hz, the response of the reactor is not point kinetic, since the shape of the induced noise deviates from the shape of the static flux, that is, from a pure cosine function. For decreasing frequencies or system sizes, the response to a localized perturbation becomes more and more point kinetic with a growing amplitude, whereas the other limit of increasing frequency or system size results in more and more localized response with a decreasing amplitude. In general, in power reactors at plateau frequencies, which is the most important parameter range of noise applications, space-dependent effects are important. Actually a one-dimensional model underestimates the importance of space-dependent effects, which are more pronounced in two- and three-dimensional cases.

In the following, the neutron noise induced by a vibrating perturbation, that is, a perturbation that originates from the variation of the position of an absorber, will be derived. Such a case is sometimes referred to as a “vibrating absorber.” A typical example is a vibrating control rod in a reactor. The control rod, whose diameter is much smaller than the core size, will be described with the same model as used in the static case, (147). Assuming that the vibrations occur with the same amplitude at each axial point, the axial dependence of the noise can be factorized and hence disregarded. Then, the problem can be treated as a two-dimensional one. The steady (i.e., not vibrating) control rod at r_p is described by

$$\Sigma_a^{\text{rod}}(\mathbf{r}) = \gamma \cdot \delta(\mathbf{r} - \mathbf{r}_p), \quad (210)$$

where $\mathbf{r}_p$ is the rod equilibrium position and γ is its Galanin's constant. When vibrating, the rod will move on a two-dimensional stochastic trajectory around the equilibrium position such that its momentary position will be given by $\mathbf{r}_p + \underline{\varepsilon}(t)$, where $|\underline{\varepsilon}(t)| \ll R$ and R is the core radius. The perturbation represented by the vibrations is given as

$$\delta\Sigma_a(\mathbf{r}, t) = \gamma [\delta(\mathbf{r} - \mathbf{r}_p - \underline{\varepsilon}(t)) - \delta(\mathbf{r} - \mathbf{r}_p)]. \quad (211)$$

Equation (211) shows that the vibrating rod is characterized by the parameters $\mathbf{r}_p$ and $\{\varepsilon_x(t), \varepsilon_y(t)\}$. The latter parameters describe the amplitude and the frequency content of the vibrations.

From (185), (205), and (211), everything is available for a formal solution except that $\delta\Sigma_a(\mathbf{r}, \omega)$ is not explicitly available since (211) cannot be Fourier transformed directly. However, performing the spatial integral in (205) first, then utilizing the smallness of the vibration amplitude through a one-term Taylor expansion in $\underline{\varepsilon}(t)$, this latter appears explicitly and can be Fourier transformed. One then obtains for the neutron noise in the frequency domain

$$\begin{aligned} \delta\phi(\mathbf{r}, \omega) &= \gamma \cdot \underline{\varepsilon}(\omega) \cdot \nabla_{\mathbf{r}_p} \{G(\mathbf{r}, \mathbf{r}_p, \omega) \cdot \phi_0(\mathbf{r}_p)\} \\ &= \gamma \cdot \{\varepsilon_x(\omega) G_x(\mathbf{r}, \mathbf{r}_p, \omega) + \varepsilon_y(\omega) G_y(\mathbf{r}, \mathbf{r}_p, \omega)\} \end{aligned} \quad (212)$$

where

$$G_x(\mathbf{r}, \mathbf{r}_p, \omega) = \frac{\partial}{\partial x_p} \{G_x(\mathbf{r}, \mathbf{r}_p, \omega) \phi_0(\mathbf{r}_p)\}, \quad (213)$$

and similarly for $G_y(\mathbf{r}, \mathbf{r}_p, \omega)$.

In a one-dimensional model, the vibrations can only take place in one direction, and the above formulas get simplified. The amplitude of the induced noise with a non-central equilibrium position of the rod is shown in ► Fig. 9. The discontinuity at the rod position is due to the interplay between the point-kinetic term and the space-dependent term. The point-kinetic term, which is proportional to the static flux, for weak rods can be taken as a cosine function (the small static dip around the rod can be neglected). The space-dependent component can be visualized with the help of the adiabatic approximation as the difference between two static fluxes, one with the equilibrium position of the rod and the other when the rod is off from the equilibrium position. The space-dependence of the shape function was solved using (148) in the case of a thin absorber. This is illustrated in ► Fig. 10.

3.3.3 Neutron Noise in Two-Group Diffusion Theory: The Local Component

Direct Approach: the Green's Function Matrix

Here, only a cursory description is given, just to illustrate the principles. Only the full solution and its Green's function will be considered, the various kinetic approximations will not be discussed. Similar to the static case, (151), a matrix and vector formalism will be used. After the usual procedure of splitting the time-dependent quantities into mean values and fluctuations,

■ Figure 9

Space-dependence of the amplitude of the noise induced by a non-central vibrating rod at $x_p = -30$ at a frequency of 1 mHz and for a Galanin constant of $\gamma = 0.01$; the discontinuity is due to the interference between the space-dependent and the point-kinetic terms

neglecting second-order terms, subtracting the static equations, and eliminating the delayed neutron precursors after a temporal Fourier transform, one obtains

$$\begin{bmatrix} D_1 \nabla^2 - \Sigma_1(\omega) & v \Sigma_{f_2}(\omega) \\ \Sigma_R & D_2 \nabla^2 - \Sigma_{a_2}(\omega) \end{bmatrix} \begin{bmatrix} \phi_1(\mathbf{r}, \omega) \\ \phi_2(\mathbf{r}, \omega) \end{bmatrix} = \begin{bmatrix} S_1(\mathbf{r}, \omega) \\ S_2(\mathbf{r}, \omega) \end{bmatrix} \quad (214)$$

The definitions of the quantities appearing in (214) are as follows:

$$\Sigma_1(\omega) = \Sigma_{a_1} + \frac{i\omega}{v_1} + \Sigma_R - v \Sigma_{f_1} \left(1 - \frac{i\omega\beta}{i\omega + \lambda} \right) \quad (215)$$

$$v \Sigma_{f_2}(\omega) = v \Sigma_{f_2} \left(1 - \frac{i\omega\beta}{i\omega + \lambda} \right) \quad (216)$$

$$\Sigma_{a_2}(\omega) = \Sigma_{a_2} + \frac{i\omega}{v_2} \quad (217)$$

$$\begin{aligned} S_1(\mathbf{r}, \omega) = & \left(\delta \Sigma_R(\mathbf{r}, \omega) + \delta \Sigma_{a_1}(\mathbf{r}, \omega) - \delta \Sigma_{f_1}(\mathbf{r}, \omega) \left(1 - \frac{i\omega\beta}{i\omega + \lambda} \right) \right) \phi_1(\mathbf{r}) \\ & - \delta \Sigma_{f_1}(\mathbf{r}, \omega) \left(1 - \frac{i\omega\beta}{i\omega + \lambda} \right) \phi_2(\mathbf{r}) \end{aligned} \quad (218)$$

■ Figure 10

The space-dependent component of the vibration noise for a Galanin constant of $\gamma = 0.01$, calculated as the difference between two static flux calculations with the rod positioned at $x_p = -30$ cm (results plotted in blue) and $x_p = -20$ cm (results plotted in red), respectively (adiabatic approximation)

and

$$S_2(\mathbf{r}, \omega) = (-\delta\Sigma_R(\mathbf{r}, \omega) + \delta\Sigma_{a_1}(\mathbf{r}, \omega)) \phi_2(\mathbf{r}) \quad (219)$$

In view of the matrix character of the equation for the noise components in the two groups, for the application of Green's function technique, one has to define a Green's matrix

$$\hat{\mathbf{G}}(\mathbf{r}, \mathbf{r}', \omega) = \begin{bmatrix} G_{1 \rightarrow 1} & G_{2 \rightarrow 1} \\ G_{1 \rightarrow 2} & G_{2 \rightarrow 2} \end{bmatrix} \quad (220)$$

where $G_{i \rightarrow j}$ is the transfer function between the noise source in group i to the neutron noise in group j . Then, the Green's matrix obeys the equation, written in symbolic form as

$$\hat{\mathbf{L}}(\mathbf{r}, \omega) \hat{\mathbf{G}}(\mathbf{r}, \mathbf{r}', \omega) = \delta(\mathbf{r} - \mathbf{r}') \hat{\mathbf{E}} \quad (221)$$

where $\hat{\mathbf{L}}(\mathbf{r}, \omega)$ is a shorthand notation for the matrix operator on the left-hand side of (214), and $\hat{\mathbf{E}}$ is the unity matrix. The noise in the two groups is then given by

$$\begin{bmatrix} \delta\phi_1(\mathbf{r}, \omega) \\ \delta\phi_2(\mathbf{r}, \omega) \end{bmatrix} = \int_{V_R} \hat{\mathbf{G}}(\mathbf{r}, \mathbf{r}', \omega) \begin{bmatrix} S_1(\mathbf{r}', \omega) \\ S_2(\mathbf{r}', \omega) \end{bmatrix} d\mathbf{r}' \quad (222)$$

In the general case, when there is a noise source present in both groups, and one is interested in the noise in both groups, all four elements of Green's matrix (220) need to be determined. The situation can be simplified if the noise source exists only in the thermal group. In that case, it is sufficient to calculate only the second column of $\hat{\mathbf{G}}$, which obeys the equation

$$\hat{\mathbf{L}}(\mathbf{r}, \omega) \begin{bmatrix} G_{2 \rightarrow 1}(\mathbf{r}, \mathbf{r}', \omega) \\ G_{2 \rightarrow 2}(\mathbf{r}, \mathbf{r}', \omega) \end{bmatrix} = \begin{bmatrix} 0 \\ \delta(\mathbf{r} - \mathbf{r}') \end{bmatrix} \quad (223)$$

This equation can be solved with a combination of the techniques used in the solution of the static matrix equation (151) and the inhomogeneous one-group equation (206) by converting the Dirac-delta function into an interface condition. The solution will be determined by the two roots $\mu^2(\omega)$ and $\nu^2(\omega)$ of the characteristic equation belonging to $\hat{\mathbf{L}}$, which is simply a frequency-dependent generalization of (153). They can be given approximately as

$$\mu(\omega) \cong B_0^2 \left(1 - \frac{k_\infty}{M^2 B_0^2 G_0(\omega)} \right); \quad M^2 = L_1^2 + L_2^2 \quad (224)$$

and

$$\nu(\omega) \approx \frac{1}{L_2} \quad (225)$$

with $L_g = D_g / \Sigma_{a_g}$; $g = 1, 2$ being the diffusion lengths. This shows that for light water power reactors at plateau frequencies, $|\nu^2| \gg |\mu^2(\omega)|$. Taking again the same non-reflected homogeneous one-dimensional system with boundaries at $x = \pm a$, the solution is given as

$$\begin{bmatrix} G_{2 \rightarrow 1}(\mathbf{r}, \mathbf{r}', \omega) \\ G_{2 \rightarrow 2}(\mathbf{r}, \mathbf{r}', \omega) \end{bmatrix} = \begin{pmatrix} 1 \\ c_\mu(\omega) \end{pmatrix} G_\mu(x, x', \omega) + \begin{pmatrix} 1 \\ c_\nu(\omega) \end{pmatrix} G_\nu(x, x', \omega) \quad (226)$$

with

$$\begin{aligned} G_\mu(x, x', \omega) &= -\frac{\Sigma_R}{D_1 D_2 \nu^2(\omega) \mu(\omega) \sin(2\mu(\omega)a)} \begin{cases} \sin[\mu(\omega)(a+x)] \sin[\mu(\omega)(a-x_0)]; & x < x_0 \\ \sin[\mu(\omega)(a-x)] \sin[\mu(\omega)(a+x_0)]; & x > x_0 \end{cases} \\ &\quad (227) \end{aligned}$$

and

$$\begin{aligned} G_\nu(x, x', \omega) &= \frac{\Sigma_R}{D_1 D_2 \nu^3(\omega) \sin(2\nu(\omega)a)} \begin{cases} \sinh[\nu(\omega)(a+x)] \sinh[\nu(\omega)(a-x_0)]; & x < x_0 \\ \sinh[\nu(\omega)(a-x)] \sinh[\nu(\omega)(a+x_0)]; & x > x_0 \end{cases} \\ &\quad (228) \end{aligned}$$

Further, $c_\mu(\omega)$ and $c_\nu(\omega)$ are the frequency-dependent extensions of the static quantities in (155):

$$c_\mu = \frac{\Sigma_R}{D_2 \mu^2(\omega) + \Sigma_{a_2} + \frac{i\omega}{\nu_2}} \quad \text{and} \quad c_\nu = \frac{\Sigma_R}{\Sigma_{a_2} + \frac{i\omega}{\nu_2} - D_2 \nu^2(\omega)} \quad (229)$$

Figure 11

Space-dependence of the amplitude of the one-dimensional Green's function in two-group diffusion theory for $x' = -30$ cm at 5 Hz in the fast group (left) and in the thermal group (right)

In (226), G_μ is the global component, representing a slow spatial relaxation, and G_ν is the local component, representing the response of the system, which exists only in the vicinity of the perturbation. As mentioned earlier, in quantitative terms, the global component is rather similar to the full solution in one-group theory, whereas the local component adds a small peak to the global component around the position of the perturbation. An illustration of the fast and the thermal components of Green's function, $G_{2 \rightarrow 1}(x, x', \omega)$ and $G_{2 \rightarrow 2}(x, x', \omega)$, respectively, is given in ► Fig. 11.

However, in the problem of largest practical importance for the local component, that is, in the interpretation of in-core neutron noise in a BWR induced by a propagating two-phase flow, the most important factor in the driving force is the fluctuations of the removal cross sections. As (218) and (219) show, the fluctuation of the removal cross section generates a noise source both in the fast group and the thermal group. To describe such a case, in the above “direct” or “forward” treatment, both columns of Green's matrix (220) need to be determined.

At the same time, in noise measurements, only the thermal noise, that is, the fluctuation of the thermal flux, is measured; hence the full information content of Green's matrix is somewhat redundant. As is also seen from (220), for such a case, it would be sufficient to determine only the second row of Green's matrix. In the direct (forward) equations used so far, this is not possible by solving one equation. These problems can be remedied by the use of adjoint (“backward”) methods, as described below.

Adjoint Approach: The Dynamic Adjoint Function

To alleviate the problems described above and for several further advantages, the concept of the dynamic adjoint function, basically the adjoint of the noise equations or that of the Green's function, was introduced by H. van Dam (1975, 1976). The adjoint operator $\hat{\mathbf{L}}^\dagger$ corresponding to direct operator $\hat{\mathbf{L}}$ given by the left-hand side of (214) is defined as one that obeys the relationship

$$(\bar{\Phi}^\dagger, \hat{\mathbf{L}}\bar{\Phi}) = (\hat{\mathbf{L}}^\dagger\bar{\Phi}^\dagger, \bar{\Phi}) \quad (230)$$

Here, $\bar{\Phi}$ and $\bar{\Phi}^\dagger$ are flux-type vectors, having a fast component and a thermal component, and both obeying the same boundary conditions of vanishing at the extrapolated boundary, and the

bracket denotes integration over the volume of the reactor. It is easy to show that in two-group diffusion theory the adjoint is simply the transposed of the direct operator, that is,

$$\hat{\mathbf{L}}^\dagger = \hat{\mathbf{L}}^T \quad (231)$$

Then, the corresponding adjoint Green's matrix $\hat{\mathbf{G}}^\dagger$ obeys the equation

$$\hat{\mathbf{L}}^\dagger(\mathbf{r}, \omega) \hat{\mathbf{G}}^\dagger(\mathbf{r}, \mathbf{r}', \omega) = \delta(\mathbf{r} - \mathbf{r}') \hat{\mathbf{E}} \quad (232)$$

Note that in (232) $\mathbf{r}'$ stand for the detection point, and the first and second members of the diagonal on the right-hand side stand for detection in the fast and the thermal group, respectively. Now if we only have a thermal detector, it is sufficient to determine the second column of the Green's matrix $\hat{\mathbf{G}}^\dagger$. Denoting this column vector as $\bar{\Psi}^\dagger$, called the dynamic adjoint for short, it obeys the equation

$$\hat{\mathbf{L}}^\dagger(\mathbf{r}, \omega) \bar{\Psi}^\dagger(\mathbf{r}, \mathbf{r}', \omega) = \begin{bmatrix} 0 \\ \delta(\mathbf{r} - \mathbf{r}') \end{bmatrix} \quad (233)$$

Then, using the properties of the adjoint, one readily obtains that with the dynamic adjoint, the noise $\delta\phi_2(\mathbf{r}, \omega)$ in the thermal group, induced by a perturbation $\bar{S}(\mathbf{r}, \omega)$ having nonzero components in both the fast and thermal groups, can be expressed as

$$\delta\phi_2(\mathbf{r}, \omega) = \int \bar{\Psi}^\dagger(\mathbf{r}', \mathbf{r}, \omega) \bar{S}(\mathbf{r}', \omega) d\mathbf{r}' \quad (234)$$

If the perturbation consists only of the fluctuations of the removal cross section, which is a good approximation for a BWR, then, as (218) and (219) show, the response of the system is determined by the scalar adjoint transfer function $\Psi_1 - \Psi_2$ (sometimes called the “removal adjoint”). The weight of the local component is enhanced in the removal adjoint as compared to the thermal direct Green's function (Behringer et al. 1979). ➤ Figure 11 gives a hint of this fact, although it refers to the direct Green's function.

The use of the dynamic adjoint has a number of further other advantages, which will not be described here. The interested reader is referred to Pázsit (1992, 2003).

As it will be seen in the next two subsections, in many cases of noise diagnostic applications, especially in conceptual ones aimed at method development, the use of a homogeneous non-reflected system in one-group theory, in one or two dimensions, is fully satisfactory. However, for concrete applications in inhomogeneous cores, the Green's function (or the dynamic adjoint), and also the induced neutron noise, need to be calculated by taking into account the inhomogeneous loading of a core. This calculation should have the same precision and spatial resolution as the known in-core fuel management (ICFM) codes. In fact, there is a way to convert existing multigroup static codes to calculate the dynamic adjoint in n -group theory. This method was used by van der Hagen et al. (1992) and tested in applications. An alternative possibility is to develop a code from scratch, dedicated to noise calculations. This alternative also was used to develop a code for the numerical calculation of the dynamic Green's function of the neutron noise and the dynamic adjoint in realistic systems in two-group diffusion theory. The code, also called as the “Neutron noise simulator” (Demazière 2004; Demazière and Pázsit 2008), takes the same input of core parameters as the ICFM code SIMULATE. Some of its applications are described in the next two subsections.

4 Applications of Power Reactor Noise Diagnostics

4.1 Unfolding Noise Source Parameters with Noise Diagnostics

In this subsection some typical applications of noise diagnostics are presented. The objective of noise diagnostics is to monitor the proper operation of nuclear reactors, the early detection of anomalies, and to identify and quantify the type of anomaly and its severity. This is achieved by unfolding the significant parameters of the perturbation $S(\mathbf{r}, \omega)$ from the measured neutron noise. One example of such parameters is the position of a localized source. The two main types of such perturbations are the absorbers of variable strength (channel-type instabilities in BWRs) and the case of vibrating absorbers. Another example is the determination of in-core flow velocity in both BWRs and PWRs. The last two examples in this subsection are the diagnostics of core-barrel vibrations and the detection of vibrating detector strings in BWRs. These last two applications, although they are based on the detection of the neutron noise as measured by ex-core and in-core neutron detectors, respectively, are not based on the dynamic response of the core to perturbations in the core. They are mentioned here only to make the list of noise methods monitoring the integrity of the core with neutron noise methods more complete.

The treatment will be based on the formalism developed in [◆ Subsect. 3.3](#). For simplicity, the basics of unfolding noise source parameters will be outlined in one-group theory with one average delayed neutron group, and the perturbation consisting of the fluctuations of the absorption cross section. Extension to two energy groups or several groups of delayed neutrons as well as fluctuations of other cross sections is straightforward. The quantitative examples in most cases were calculated by the neutron noise simulator, unless specified otherwise.

As described earlier, the equation for the neutron noise, induced by the fluctuation of the absorption cross sections, reads as

$$\nabla^2 \delta\phi(\mathbf{r}, \omega) + B^2(\omega) \delta\phi(\mathbf{r}, \omega) = \frac{S(\mathbf{r}, \omega)}{D}, \quad (235)$$

where

$$S(\mathbf{r}, \omega) = \delta\Sigma_a(\mathbf{r}, \omega) \phi_0(\mathbf{r}). \quad (236)$$

The solution is given with the Green's function or system transfer function $G(\mathbf{r}, \mathbf{r}', \omega)$, which is obtained from the equation

$$\nabla^2 \delta\phi(\mathbf{r}, \omega) + B^2(\omega) \delta\phi(\mathbf{r}, \omega) = \frac{\delta(\mathbf{r} - \mathbf{r}')}{D} \quad (237)$$

as

$$\delta\phi(\mathbf{r}, \omega) = \int G(\mathbf{r}, \mathbf{r}', \omega) S(\mathbf{r}', \omega) d\mathbf{r}'. \quad (238)$$

[Equation \(238\)](#) is the basis of core diagnostics with neutron noise methods. It shows that the effect of a perturbation can be factorized into a noise source term $S(\mathbf{r}, \omega)$, and a system transfer $G(\mathbf{r}, \mathbf{r}', \omega)$. As [\(237\)](#) shows, the system transfer function is only dependent on the parameters of the unperturbed system, which is a consequence of using linear theory. The transfer function

$G(\mathbf{r}, \mathbf{r}', \omega)$ can thus be calculated for a reactor independently of the type of perturbation. Hence, $G(\mathbf{r}, \mathbf{r}', \omega)$ can be assumed to be known in a diagnostic task.

The task of diagnostics is to quantify the noise source $S(\mathbf{r}, \omega)$ from the measured neutron noise $\delta\phi(\mathbf{r}, \omega)$, using the knowledge of the transfer function. Determining $S(\mathbf{r}, \omega)$ from $\delta\phi(\mathbf{r}, \omega)$ through (238) is an inverse task. Formally, if $\delta\phi(\mathbf{r}, \omega)$ and $G(\mathbf{r}, \mathbf{r}', \omega)$ are known as continuous functions of the space coordinates, (238) is a Fredholm-type integral equation for the unknown $S(\mathbf{r}, \omega)$, which may be inverted.

However, a difficulty arises here since $\delta\phi(\mathbf{r}, \omega)$ is only known in a few discrete points, that is, in the detector positions. If nothing is known about $S(\mathbf{r}, \omega)$, inversion of (238) has only a chance if a relatively large number of detectors are available at a time, which is normally not the case in practice. Thus, usually another approach is selected. First, by inspecting the signals of the neutron detectors available, a guess is made on the type of perturbation giving rise to the detected noise (such as, two-phase flow transport, vibrations). Such assumptions are usually made by studying the frequency content of the measured noise and the phase relationships between the detectors, or the type of noise source may be apparent from other, independent measurements. A given noise source is then represented by a simple functional form, in which only a few parameters remain as unknowns. Then, it may be possible to determine those few parameters by using a few neutron detectors.

For an illustration, the case of the neutron noise induced by a central “absorber of variable strength,” as well as that of a vibrating absorber will be considered in a two-dimensional cylindrical geometry (► Fig. 12 and ► 13, respectively). In both figures, the surface plots show the full space-dependence of the amplitude (left figures) and phase (right figures) of the noise as calculated by the noise simulator. The black dots represent the possible locations of five in-core neutron detectors together with the value of the amplitude and phase of their measured signals. It can clearly be seen from these figures, that the neutron noise recorded from these five detectors does not allow a direct determination of the location of the noise source, which is responsible for the measured neutron noise. However, the type of the noise source (either an “absorber of variable strength” or a “vibrating absorber”) can be determined from the phase of the neutron noise. In case of an “absorber of variable strength,” the phase does not vary much throughout the core, whereas the phase varies from 0° to -180° in case of a “vibrating absorber.” In this case, a mono-directional vibration along a line was assumed, leading to the clear phase differences seen in ► Fig. 13. In reality, the situation is even more complicated since the vibration is usually a two-dimensional random walk, but still similar conclusions can be drawn regarding the type of the noise source. Once the type of the source is decided, a simple model of the noise source can be set up, which can be used to elaborate an algorithm for the determination of the position of the source (“localization”).

4.1.1 Localization of Absorbers of Variable Strength

Although the terminology here refers to absorbers, these types of noise sources encompass all kinds of cross sections, that is, absorption, fission, and scattering. Absorbers of variable strengths can be represented as fluctuations in the macroscopic absorption cross sections at a given fixed location $\mathbf{r}_0$ and the corresponding noise source expressed as

$$\delta\Sigma_a(\mathbf{r}, \omega) = \gamma(\omega)\delta(\mathbf{r} - \mathbf{r}_0) \quad (239)$$

■ Figure 12

Calculated (surface plot) and simulated measured (black dots) values of the neutron noise induced by a central (localized) “absorber of variable strength” in the thermal group at a frequency of 1 Hz

■ Figure 13

Calculated (surface plot) and simulated measured (black dots) values of the neutron noise induced by a central “vibrating absorber” in the thermal group at a frequency of 1 Hz

where $\gamma(\omega)$ is the noise source strength, which might be frequency-dependent in the most general case.

The neutron noise induced by such a noise source can be formally expressed as

$$\delta\phi(\mathbf{r}, \omega) = \int G(\mathbf{r}, \mathbf{r}', \omega) \delta\Sigma_a(\mathbf{r}', \omega) \phi_0(\mathbf{r}') d\mathbf{r}' \quad (240)$$

which, due to (239), becomes

$$\delta\phi(\mathbf{r}, \omega) = \gamma(\omega) G(\mathbf{r}, \mathbf{r}_0, \omega) \phi_0(\mathbf{r}_0) \quad (241)$$

If one now assumes that the neutron noise is measured at two locations $\mathbf{r}_A$ and $\mathbf{r}_B$ within the core, then taking the ratio between the two neutron noise signals allows eliminating the noise

source strength $\gamma(\omega)$. That is, one has

$$\frac{\delta\phi(\mathbf{r}_A, \omega)}{\delta\phi(\mathbf{r}_B, \omega)} = \frac{G(\mathbf{r}_A, \mathbf{r}_0, \omega)}{G(\mathbf{r}_B, \mathbf{r}_0, \omega)} \quad (242)$$

The left-hand side of (242) can be obtained from measurements. The right-hand side contains the unknown of the problem, namely the location $\mathbf{r}_0$ as an unknown argument of a known function, since the transfer function can be calculated. Scanning all possible values for $\mathbf{r}_0$ thus offers the possibility of constructing a localization procedure, aiming at determining the actual location of the noise source. When there is equality between the left-hand side and the right-hand side, that is, between the measured quantity and the calculated one, the noise source has been correctly located.

In a two-dimensional case, which is what one encounters in practice since due to the core geometry, usually only the radial position of a fuel assembly or a control rod is searched, two detectors are not sufficient for the localization since there will be a whole set of $\mathbf{r}_0$ values, lying on a line, which will satisfy (242). At least three detectors are needed, or more. If one has access to several detectors, the following quantity can be evaluated for each detector combination (A, B):

$$\Delta_{A,B}(\mathbf{r}) = \frac{\delta\phi(\mathbf{r}_A, \omega)}{\delta\phi(\mathbf{r}_B, \omega)} - \frac{G(\mathbf{r}_A, \mathbf{r}, \omega)}{G(\mathbf{r}_B, \mathbf{r}, \omega)} \quad (243)$$

so that the minimum of the following function should correspond to the location $\mathbf{r}_0$ of the noise source:

$$\Delta(\mathbf{r}) = \sum_{A,B} \Delta_{A,B}^2(\mathbf{r}) \quad (244)$$

Since it is common practice to use the auto- and cross-power spectral densities (APSDs and CPSDs respectively) of the measured signals instead of their Fourier transform, (243)–(244) have to be written as follows:

$$\Delta_{A,B,C,D}(\mathbf{r}) = \frac{CPSD(\mathbf{r}_A, \mathbf{r}_B, \omega)}{CPSD(\mathbf{r}_C, \mathbf{r}_D, \omega)} - \frac{G(\mathbf{r}_A, \mathbf{r}, \omega) \times G^*(\mathbf{r}_B, \mathbf{r}, \omega)}{G(\mathbf{r}_C, \mathbf{r}, \omega) \times G^*(\mathbf{r}_D, \mathbf{r}, \omega)} \quad (245)$$

and

$$\Delta(\mathbf{r}) = \sum_{A,B,C,D} \Delta_{A,B,C,D}^2(\mathbf{r}) \quad (246)$$

Despite the apparent high number of possible detector combinations, the number of detectors quadruplets that need to be taken into account can be significantly reduced if the redundant combinations are discarded. The location of the perturbation is then found at the value of $\mathbf{r}$ for which the right-hand side of (246) yields a minimum.

As mentioned earlier, if the system behaves in a point-kinetic manner, the space-dependence of the induced neutron noise is given by the static neutron flux, and thus does not depend on the location of the noise source. In such a case, the localization algorithm cannot be applied. As mentioned earlier, and as is seen in  Fig. 12, large systems significantly deviate from point kinetics for large enough frequencies (above 0.1 Hz), so that the localization algorithm can be used for such frequencies.

The localization algorithm was first developed using an analytical Green's function corresponding to a homogeneous reactor in one-group diffusion theory (see Kitamura et al. 1999) and later using a numerical Green's function corresponding to a heterogeneous reactor in two-group diffusion theory, that is, using the neutron noise simulator (Demazière 2006). The algorithm was also tested on real plant data, namely the Forsmark-1 channel instability event in 1996/1997 in Sweden (see Kitamura et al. 1999; Demazière 2006). In 1996, during the start-up tests of the Forsmark-1 BWR for the fuel cycle 16, local instabilities were detected at reduced power and reduced core flow. As it was clarified later, the instability was due to local density wave oscillation (DWO) in a fuel assembly, which was not properly seated on the bottom plate ("unseated" assembly). The task of the localization was to identify the unseated assembly.

During this stability measurement, the lower plane of the core was rather well equipped with local power range monitors (LPRMs) (27 of the 36 available detector strings were actually recorded). A closer look at the phase of the measured flux noise indicated that the neutron noise was driven by a local noise source, similar to the effect of an absorber of variable strength (reactor oscillator), rather than a moving absorber, such as a vibrating control rod. The localization algorithm presented above was thus applied to these measurement data in a two-dimensional representation of the core and the results are shown in  Fig. 14. The noise source pointed out by the localization algorithm is very close to a fuel assembly, which was discovered to be

 **Figure 14**

Result of the localization algorithm in the Forsmark-1 case (local instability event). The unseated fuel element is marked with a square, and the noise source identified by the localization algorithm with a circle; the detectors that were used in the localization search are marked by white crosses, whereas the detectors that were not used are marked by black crosses

unseated during the fuel outage following the fuel cycle 16. Hence, the localization procedure worked rather well for this case.

4.1.2 Localization of Vibrating Control Rods

The fact that a vibrating control rod leads to detectable neutron noise is known from the ORR and HFIR reactors (Fry 1971). This meant that at least the occurrence of stronger than normal vibrations could be detected by neutron noise measurements. Later it turned out that control rod vibrations can occur even in power reactors. Since excessive vibration is always a sign of beginning malfunction, detecting and locating vibrations by neutron noise methods became an interesting task.

Compared to the absorber of variable strength, the vibrating absorber represents a very different perturbation and the neutron noise it generates, and hence also the expressions to be inverted, are also very different from that of the absorber of variable strength. The difference in the noise source can be seen by comparing (239) with (211), whereas the difference in the space-dependence of the noise is seen by comparing  Fig. 12 with  Fig. 13. Not surprisingly, also the localization algorithm will be rather different.

As already described in  3.3.2, the perturbation represented by a thin vibrating rod in two dimensions can be represented by the fluctuation of the absorption cross sections as

$$\delta\Sigma_a(\mathbf{r}, t) = \gamma [\delta(\mathbf{r} - \mathbf{r}_p - \underline{\varepsilon}(t)) - \delta(\mathbf{r} - \mathbf{r}_p)] \quad (247)$$

where $\mathbf{r}_p$ is the equilibrium position to be determined by the diagnostics, and $\underline{\varepsilon}(t)$ is the two-dimensional displacement from the equilibrium position. As it was also shown, the neutron noise induced by such a noise source is given as

$$\begin{aligned} \delta\phi(\mathbf{r}, \omega) &= \gamma \cdot \underline{\varepsilon}(\omega) \cdot \nabla_{\mathbf{r}_p} \{G(\mathbf{r}, \mathbf{r}_p, \omega) \cdot \phi_0(\mathbf{r}_p)\} \\ &= \gamma \{ \varepsilon_x(\omega) G_x(\mathbf{r}, \mathbf{r}_p, \omega) + \varepsilon_y(\omega) G_y(\mathbf{r}, \mathbf{r}_p, \omega) \} \end{aligned} \quad (248)$$

where

$$G_x(\mathbf{r}, \mathbf{r}_p, \omega) = \frac{\partial}{\partial x_p} \{G(\mathbf{r}, \mathbf{r}_p, \omega) \cdot \phi_0(\mathbf{r}_p)\}, \quad (249)$$

and similarly for $G_y(\mathbf{r}, \mathbf{r}_p, \omega)$.

Equation (248) shows that the vibration components ε_x and ε_y , which are of no direct interest, appear explicitly in the noise expression, whereas the rod position $\mathbf{r}_p$, the main interest of the diagnostics, is contained implicitly. It is also seen that merely taking the ratios of detector signals will eliminate the unknown rod strength γ , but will not eliminate the displacement components. To determine $\mathbf{r}_p$, a more involved procedure is necessary in which the unknown vibration components are eliminated.

Such a localization procedure can be constructed as follows. One selects three detectors at positions $\mathbf{r}_i$, $i = 1, 2, 3$, possibly with an azimuthally evenly spread arrangement as in  Fig. 15. Denoting the detector signals of the three detectors as $\phi(\mathbf{r}_i, \omega) \equiv \phi_i(\omega)$, $i = 1, 2, 3$, one has

$$\delta\phi_i(\omega) = \gamma \{ \varepsilon_x(\omega) G_{i,x}(\mathbf{r}_p, \omega) + \varepsilon_y(\omega) G_{i,y}(\mathbf{r}_p, \omega) \}, \quad (250)$$

■ Figure 15

Core layout of the Hungarian Paks-2 PWR with the locations of neutron detectors and control rods

for all three signals, with

$$G_{i,\alpha}(\mathbf{r}_p, \omega) \equiv G_{\alpha}(\mathbf{r}_i, \mathbf{r}_p, \omega); \quad \alpha = \{x, y\}. \quad (251)$$

Using two equations of the type (250) to express the displacement components in terms of the measured noise and the transfer functions $G_{i,\alpha}(\mathbf{r}_p, \omega)$, and substituting these in the third equation results in an expression of the form

$$F_1(\mathbf{r}_p, \omega)\delta\phi_1(\omega) + F_2(\mathbf{r}_p, \omega)\delta\phi_2(\omega) + F_3(\mathbf{r}_p, \omega)\delta\phi_3(\omega) = 0. \quad (252)$$

Here,

$$F_1(\mathbf{r}_p, \omega) = G_{2x}G_{3y} - G_{2y}G_{3x}, \quad (253)$$

and similarly for $F_2(\mathbf{r}_p, \omega)$ and $F_3(\mathbf{r}_p, \omega)$.

Equation (252) constitutes the formal solution of the localization problem. Its use is similar to that of (243) and (244): the $\phi_i(\omega)$ are taken from the measurements, and the functional form of the $F_i(\mathbf{r}_p, \omega)$ is known from theory. In this equation, all quantities are known except the argument $\mathbf{r}_p$, that is, the searched rod position. The equation is only fulfilled if $\mathbf{r}_p$ has the correct value, this parameter is thus determined as a root of the equation. The localization in a given case is thus performed as finding the root of the complex equation (252).

In practice, however, it is not the Fourier transforms of the signals that are used, rather the auto- and cross-spectra of the $\delta\phi_i$, that is, $APSD_{\delta\phi_i}(\omega)$ and $CPSD_{\delta\phi_i, \delta\phi_j}(\omega)$, respectively, are used. Likewise, instead of $\varepsilon_x(\omega)$ and $\varepsilon_y(\omega)$, the auto- and cross-spectra, $S_{xx}(\omega)$, $S_{yy}(\omega)$, and $S_{xy}(\omega)$ of the displacement components need to be used as input source. With the application

of the Wiener–Khinchin theorem, the auto- and cross-spectra of the detector signals can be expressed from (250) as

$$APSD_{ii}(\omega) = APSD_{\delta\phi_i}(\omega) = \gamma^2 \{G_{ix}^2 S_{xx} + G_{iy}^2 S_{yy} + 2G_{ix}G_{iy}G_{xy}\}, \quad (254)$$

$$CPSD_{ij}(\omega) = CPSD_{\delta\phi_i, \delta\phi_j}(\omega) = \gamma^2 \{G_{ix}G_{jy}S_{xx} + G_{iy}G_{jy}S_{yy} + (G_{ix}G_{jy} + G_{jx}G_{iy})S_{xy}\}, \quad (255)$$

In the above form, for simplicity, it was assumed that we are on the plateau frequency region and can assume Green's function and the vibration displacement cross-spectra as real. The latter is the consequence of the decoupled character of the vibrations along two main axes.

In this form, the localization procedure now requires eliminating the vibration spectra $S_{xx}(\omega)$, etc., and deriving an equation similar to (252) in which only the transfer functions and the neutron noise spectra are present. Such an equation can be formally written down with the help of the spectral and transfer matrices in the form

$$\mathbf{G}_{12}^{-1}(\mathbf{r}_p) \mathbf{S}_{12} \mathbf{G}_{12}^{+-1}(\mathbf{r}_p) = \mathbf{G}_{23}^{-1}(\mathbf{r}_p) \mathbf{S}_{23} \mathbf{G}_{23}^{+-1}(\mathbf{r}_p) = \mathbf{G}_{13}^{-1}(\mathbf{r}_p) \mathbf{S}_{13} \mathbf{G}_{13}^{+-1}(\mathbf{r}_p), \quad (256)$$

where

$$\mathbf{S}_{ij} \equiv \begin{bmatrix} APSD_{ii}(\omega) & APSD_{ji}(\omega) \\ CPSD_{ij}(\omega) & APSD_{jj}(\omega) \end{bmatrix}; \quad i, j = 1, 2, 3, \quad (257)$$

is the neutron noise spectral matrix, and

$$\mathbf{G}_{ij} = \begin{bmatrix} \mathbf{G}_{ix} & \mathbf{G}_{jx} \\ \mathbf{G}_{iy} & \mathbf{G}_{jy} \end{bmatrix}, \quad (258)$$

is the transfer function matrix. The rod position $\mathbf{r}_p$ is still given as the root of (256). For finding its root, the equation has to be split up into scalar equations, and the simultaneous root of the several equations has to be found.

It is seen that, in contrast to locating a variable strength absorber, this method is much more complicated. Despite these difficulties, the method was applied with success to the localization of an excessively vibrating control rod in the Hungarian Paks-2 PWR (Pázsit and Glöckler 1988).

As an alternative to the above complicated algorithmic procedure, another method based on artificial neural networks (ANNs) may be used (Pázsit et al. 1996). ANNs are being increasingly used in all kinds of diagnostics that require the solution of inverse tasks (Pázsit and Kitamura 1996). Their principle of operation is that they need a certain number of training samples, in this case sets of neutron noise and rod position data that belong together. Such data are generated by model calculations, using the same transfer functions as in the algorithmic method.

To this end a model of the two-dimensional vibrations, or rather a model for the noise source spectral matrix with elements $S_{\alpha\beta}$ with $\alpha, \beta = x, y$, for example, $S_{xx} = APSD_{\varepsilon_x}(\omega)$, etc. is needed. In the simplest nontrivial random model the two-dimensional vibrations can be parametrized by two variables, an ellipticity (anisotropy) parameter $k \in [0, 1]$ and the preferred

direction of the vibration $\alpha \in [0, \pi]$ as

$$S_{xx} \propto 1 + k \cos 2\alpha, \quad (259)$$

$$S_{yy} \propto 1 - k \cos 2\alpha, \quad (260)$$

$$S_{xy} = S_{yx} \propto k \sin 2\alpha. \quad (261)$$

Then, a large number of training data are generated, and the ANN is trained to recognize the correct control rod position. When the training is finished, the ANN is ready to take measured data as its input, and it will designate one of the rods as the vibrating one.

Both the algorithmic and the ANN-based method were tested in a real measurement. This concrete application concerns the excessive vibration of a control rod in the Hungarian Paks-2 PWR in 1985. Details of the event are described in Pázsit and Glöckler (1988). Both the algorithmic and the ANN-based methods were tested, and they both pointed out correctly rod #4, which was the vibrating one. It is interesting to note that detector #1 (SPND string 04-37) (see ► Fig. 15), being much closer to the vibrating rod #4 as the other two detectors, gave a slightly smaller vibration peak in its APSD as the other two detectors. This is due to the interplay of the point-kinetic and space-dependent terms of the vibration-induced noise, as shown earlier. This fact also shows that localization of a vibrating rod cannot be based on simple intuition.

4.1.3 Flow Velocity Estimations

Being able to monitor in-core coolant velocity as well as two-phase flow is of prime importance in order to detect at a very early stage any flow blockage/reduction inside the core due to debris, formation of crud, etc., before it leads to fuel damage. Western-type light water reactors are usually not equipped with in-core flow meters allowing the determination of the coolant velocity within the fuel assemblies. Nevertheless, the core is usually instrumented with in-core neutron detectors and in some cases in-core temperature detectors. If pairs of such detectors are located in the same fuel assembly, any fluctuation in the coolant flow will be registered by each of the two detectors within the same fuel assembly with some time delay. The measurement of this time delay allows estimating the coolant flow, knowing the axial separation distance between the detectors. Such methods and their applications will be described below.

Flow Velocity Estimations in BWRs from the Neutron Noise

It was noted in the early 1970s that neutron detectors in the same instrument tube in a BWR can measure the transport time of two-phase flow between two detectors from the phase of the cross-spectrum (Wach and Kosály 1974). The perturbation in this case is represented by the density fluctuations in the coolant, in form of a two-phase flow with a random spatial structure (propagating bubbles). To explain the measurements, first the existence of the local component of the induced noise was postulated (Wach and Kosály 1974), then the local component was derived by the use of two-group diffusion theory (Kosály 1975). The appearance of the local and global components of the noise in the Green's function was outlined in ► Subsect. 3.3.3.

It is important that in the case of BWR in-core noise, these two components give a comparable contribution to the detector signal, that is, none of them suppresses the other completely. Rather, their joint occurrence leads to interference effects as described below.

In a simplified picture, for the local component one can assume that

$$G(\mathbf{r}, \mathbf{r}', \omega) \approx \delta(\mathbf{r} - \mathbf{r}'), \quad (262)$$

that is,

$$\delta\phi_L(\mathbf{r}, t) \approx \delta\Sigma(\mathbf{r}, t)\phi_0(\mathbf{r}) \quad (263)$$

where the subscript L indicates that this refers to the local component only. If only this component existed, then the signal of two detectors placed along an axial line at a distance $z_2 - z_1$ to each other would have signals similar to each other but with a time delay

$$\tau = \frac{z_2 - z_1}{v} \quad (264)$$

where v is the propagation velocity. That is,

$$\delta\phi_L(z_2, t) = \delta\phi_L(z_1, t - \tau). \quad (265)$$

In the frequency domain, this leads to

$$\delta\phi_L(z_2, \omega) = \exp(-i\omega\tau)\delta\phi_L(z_1, \omega) \quad (266)$$

Applying the Wiener–Khinchin theorem and using (266), the cross-spectrum between the two detectors can be expressed by the auto-spectrum of one of the signals as

$$\begin{aligned} CPD_{\phi_L}(z_1, z_2, \omega) &\cong \delta\phi_L(z_2, \omega)\delta\phi_L^*(z_1, \omega) = \delta\phi_L(z_1, \omega)\delta\phi_L^*(z_1, \omega) \times \exp(-i\omega\tau) \\ &= APSD_{\phi_L}(z_1, \omega) \times \exp(-i\omega\tau) \end{aligned} \quad (267)$$

According to (267), the phase of the cross-spectrum is a linear function of ω

$$\varphi(\omega) = -\omega\tau \quad (268)$$

from which the transit time τ of the propagation of the perturbation can be determined, and its mean velocity can then be inferred from (264).

Since the boiling process itself, to a good approximation, is usually a white noise, $APSD_{\phi}(z, \omega)$ and thus $|CPD_{\phi}(z_1, z_2, \omega)|$ are constants in the frequency range of interest, usually between 0.1 and 10–15 Hz in a typical BWR. If (265) holds, that is the two signals are identical except for a time delay, then the coherence equals unity:

$$\text{Coh} \equiv \frac{|CPD_{\phi_L}(z_1, z_2, \omega)|}{[APSD_{\phi_L}(z_1, \omega) \times APSD_{\phi_L}(z_2, \omega)]^{1/2}} = 1 \quad (269)$$

In reality, however, the two signals will not be identical due to generation, collapse, and coagulation of the bubbles between z_1 and z_2 , and there are always other, independent noise sources in the core. For all these reasons the coherence will be less than unity. Another, more significant fact is that in all reactors there is a so-called reactivity noise or global noise present, which is

in-phase in the signal of the two detectors. This reactivity noise is generated, for example, by the collective movement, generation, and collapse of all bubbles inside the whole reactor. This component can be described, for the present purposes, as their time-dependence being equal in the two detector signals. This can also be expressed in the frequency domain as

$$\delta\phi_G(z_1, \omega) = \delta\phi_G(z_2, \omega) = C \cdot A(\omega) \quad (270)$$

where, for simplicity, we assumed that the amplitude of the two components are equal. The total signal measured by the detectors at z_1 and z_2 are then given as

$$\delta\phi(z_1, \omega) = \delta\phi_L(z_1, \omega) + C \cdot A(\omega) \quad (271)$$

and

$$\delta\phi(z_2, \omega) = \delta\phi_L(z_1, \omega) \exp(-i\omega\tau) + C \cdot A(\omega) \quad (272)$$

Assuming that the local and global components are uncorrelated, that is, their cross-power spectrum is zero, and assuming the frequency-dependence of both the local component and the global component as constants, a simple algebra yields the result that the coherence of the total noise as measured at z_1 and z_2 as well as the CPSD will have an oscillating structure. They will have maxima at

$$\omega\tau = 2n\pi \quad \text{for } n = 0, 1, 2, \dots \quad (273)$$

and minima at

$$\omega\tau = (2n+1)\pi \quad \text{for } n = 0, 1, 2, \dots \quad (274)$$

Likewise, the phase will also deviate from the linear dependence on ω , which is shown in (268). Rather, it will slightly oscillate around the linear dependence with the same periodicity as the coherence in (273), crossing the true linear phase value periodically. Such an effect is clearly seen in some measurements (Wach and Kosály 1974).

For the sake of illustration, some measurements are shown here from the Swedish BWR Barsebäck-2 in ► Fig. 16. The slopes of the straight lines, representing the phase of the CPSD, are suitable to determine the transit time of bubbles between two axially placed detectors. It is also seen, from the change of the slope of the phase, that the transit time decreases with increasing axial height of the detectors, due to higher steam velocity in the upper part of the core. The coherence shows a behavior completely consistent with (273) and (274); that is, it has maxima at the zero-crossings and minima at the π -crossings of the phase. This way the void transit time between two detectors can be determined, and a modest axial resolution of this quantity (in the three consecutive pairs of the four detectors) can be obtained.

Flow velocity Estimations in PWRs from Temperature and Neutron Noise

Historically, first the possibility of using temperature fluctuations for the measurement of water flow in a pipe, such as the feedwater flow of a PWR, was investigated (Kosály and Meskó 1972a). A number of cross-correlation methods, using temperature, N-16 and ultrasound signals have been developed for measuring the feedwater flow, but these will not be discussed here. The

■ Figure 16

Phase and coherence between detectors in a detector string of the Swedish BWR Barsebäck-2

method of temperature fluctuations is taken up here partly because it can be used for measuring the core flow as well, and because it gives a background to the neutron noise-based methods of measuring coolant flow velocity in the core.

Measurements of temperature fluctuations in the coolant are local; hence such a method is equivalent to using only the local component mentioned earlier in this subsection. The measurement would lead to a linear phase whose slope yields the transit time. Alternatively, the maximum of the cross-correlation function (CCF), and a number of more refined methods, can be used. If the temperature pattern in the coolant changes when passing from one thermocouple to another, due to thermal convection, turbulence, etc., then the phase will deviate from strictly linear, and the cross-correlation function gets asymmetric.

Coolant flow measurements based on in-core temperature in PWRs are not common, due to lack of instrumentation. One example is given here for illustration, from measurements taken in the Swedish Ringhals-2 PWR. This reactor was equipped with 108 gamma-thermometers (GTs) installed permanently in the core. These detectors were distributed in 12 detector strings, each of them containing 9 GTs located at different axial levels and covering the whole core active height (► Fig. 21). Although these detectors are meant primarily to detect the gamma flux, in the frequency range 0.1–1 Hz they measure the coolant temperature fluctuations.

An illustrative example of the phase delay observed between two GTs within the same fuel assembly is given in ► Fig. 17, as well as the flow velocity estimated from the phase delay between several combinations of pairs of GTs within the same fuel assembly. The flow velocity estimations are also compared to values computed by the static core simulator SIMULATE-3. The inaccuracy observed in the estimated flow compared to the SIMULATE-3 values is due to possible differences in time constants of the cold junction of the GTs. Cross-correlation techniques are further complicated by the fact that they usually require expert knowledge and expert opinion, which prevents from applying them in an automated manner. More details can be found in Demazière and Pázsit (2002).

From the point of instrumentation, a better choice is to use in-core LPRMs or fission chambers, since many reactor types are equipped with such detectors. These can detect the effect of

■ Figure 17

Phase of the cross-power spectral density (CPSD) between a pair of gamma-thermometers (GTs) located at different axial locations (*left*) and flow velocity estimations (*right*) in the Ringhals-2 PWR

propagating temperature fluctuations on the neutron field. However, the influence of the minute temperature fluctuations on the neutron field is several orders of magnitude smaller than the effect of the two-phase flow. Hence in such measurements the global component, in form of general background noise, or even the global effect of temperature fluctuations, dominates totally. Indeed, in the early days one investigated only the reactivity effect of coolant inlet temperature fluctuations (Kosály and Meskó 1972b). Dominance of the global term results in a close to zero phase of the cross-correlation function, and on the first sight the task of measuring the velocity may appear impossible. In fact, in the first attempts to measure coolant flow velocity by in-core neutron detectors, the oscillation of the phase around zero was used to estimate the velocity (Pór 1981).

However, there is a possibility to largely eliminate the effect of the global component and enhance the information content of the cross-correlation measurement. The trick is to use, instead of the cross-correlation function (CCF) the inverse Fourier transform of the cross-spectrum divided by the auto-spectrum of one of the detectors, also called impulse response function (ICF):

$$IMP_{21}(t) = FFT^{-1} \left\{ \frac{CPSD_{21}(\omega)}{APSD_1(\omega)} \right\} \quad (275)$$

This procedure largely eliminates the contribution from the global component, and the impulse response function so determined is amenable to extract the flow velocity in PWR in-core noise measurements (Adorján et al. 2000; Pór et al. 2003).

Such measurements clarified in the Hungarian PWR Paks-2 that the reason for core power asymmetry laid in the asymmetric flow velocities in the core, due to crud building on the lowest spacers. A graphical representation of the velocity distribution over a horizontal cross section of the core of Paks-2 is shown in ► Fig. 18. Such measurements are occasionally performed at other plants.

4.1.4 Miscellaneous Other Applications

Two further methods will be described briefly in which neutron noise is used to identify and quantify core processes with the aim of detecting deterioration of the core integrity. These are core-barrel vibrations and vibrations and impacting of BWR in-core detector tubes. In both cases, there is no core dynamics involved, the detectors act merely as displacement sensors, even if with an unknown scaling. These methods are described here only for sake of completeness.

Diagnostics of Core-Barrel Vibrations in PWRs

In PWRs, the core barrel is a structure hanging vertically inside the reactor pressure vessel from its top. A layout of the reactor internals for a typical PWR is given in ► Fig. 19. The core barrel is exposed to pressure fluctuations of the turbulent flow in the downcomer and in the core, hence it executes small vibrations in the deep submillimeter range. Several modes of oscillations of the core barrel are usually encountered. The two most common ones are the pendular or beam-mode vibration, and the shell-mode vibration, as illustrated in ► Fig. 20. Since the downcomer is in between the core and the detectors, the vibrations of the core lead to changes in the water thickness between the core and the detectors, hence to a changed attenuation. Due to this, for small vibrations, the detectors act as displacement sensors of the corresponding components of the motion, as can be inferred from ► Fig. 20. The eigenfrequency of the beam-mode is around

■ Figure 18

Asymmetric velocity profile in the core of Paks-2 (From Adorján et al. 2000)

8 Hz, whereas for the shell-mode vibration the eigenfrequency is about 20 Hz. These vibrations can be measured by accelerometers, and even by pressure sensors, but these are usually not available at operating plants, only during the preoperational tests. The core-barrel vibrations are most commonly detected by ex-core neutron detectors. ➤ Figure 21 shows the arrangement of the eight ex-core detectors, four detectors placed with equal spacing azimuthally around the core at two different axial elevations.

Monitoring of the beam-mode/shell-mode vibrations is performed by using the signals from the ex-core and/or in-core neutron detectors and analyzing the information in the amplitude of the peaks corresponding to the vibration modes of interest, mostly the beam-mode vibrations, and the phase relationships between the detectors. Taking into account the symmetry of the various vibration modes, with various combinations of the four ex-core detectors, the effect of a selected mode can be enhanced and the others suppressed. The details of this procedure will not be described here, the interested reader is referred to Pázsit and Glöckler (1998) for more details. An illustration of the separation of the modes and the resulting spectra are shown in ➤ Fig. 22.

■ Figure 22

Spectra from ex-core detector signals from a measurement made at the Swedish Ringhals-3 PWR (the beam-mode and shell-mode components are shown separately)

■ Figure 23

Auto-power spectral density (APSD) of the separated beam-mode component, and the results of a curve-fitting procedure using an analytical expression of the peaks (*left*), and the separation of the individual peaks in the curve-fitting procedure (*right*)

In order to obtain the amplitude of the peaks more objectively, and in order to resolve closely lying peaks, the vibration peaks in the beam-mode/shell-mode spectra can be fitted to an analytical expression of the peak, from which the amplitude of the peaks, the peak frequencies, and the widths of the peaks can be determined by curve fitting. Following these parameters during the life of a nuclear reactor allows characterizing the evolution of the amplitude of the beam-mode/shell-mode vibrations, from which early material degradation can be detected. A curve fitting to one of the recent measurements in Ringhals-4 is shown in ► Fig. 23 (left figure). The right figure illustrates the decomposition of closely lying vibration peaks into individual components, to enhance the determination of the magnitude of the beam-mode components in an accurate way (Pázsit et al. 2008). In ► Fig. 24, the long-term evolution of the vibration amplitudes is shown for the Ringhals reactors during the period 1991–1998 (Karlsson and Pázsit 1998).

It has to be noted that this type of analysis is hampered by the fact that the individual vibrations of fuel assemblies in the core give a contribution to the signal of the closest detector, which disturbs the symmetry of the detector signals arising from the symmetries of the various core-barrel vibration modes, hence it interferes with the mode decoupling procedure. Further, it also disturbs a precise determination of the amplitudes of the core-barrel vibrations.

Detection of Impacting Detector Strings in BWRs

Flow-induced vibrations of the detector tubes in BWRs are a possible safety concern when the vibration amplitude is such that the detector tubes impact with the neighboring fuel boxes. Impacting can damage the fuel boxes, which may also cause damage to the fuel cladding. The vibrations arise from the strong flow of cooling water in the reactor and the fact that the detector tubes, which are roughly four meters long, are fixed only in their ends. ► Figure 25 shows the configuration of a detector tube together with the surrounding fuel assemblies.

The principle of the detection is based on the signal of the vibrating detector itself. Apart from the effect of other noise sources and general background, vibration of a detector in a flux

Figure 24

Trend behavior of the vibration amplitudes in some of the Swedish Ringhals PWRs during 1991–1998

Figure 25

Illustration of a detector tube in a boiling water reactor (BWR) core with four surrounding fuel assemblies

gradient will lead to a signal proportional to the displacement of the detector, as indicated in [Fig. 26](#). A direct scaling of the detector current to absolute displacements is though not possible, since usually neither the flux gradient, nor the direction of the vibrations (or the vibration trajectory) is known.

■ Figure 26

Illustration of the origin of the different components of the detector signal, arising from the vibration in a flux gradient, background noise, and impacting on a fuel assembly

As ► Fig. 26 shows, it is assumed that when impacting occurs, a short-lived, transient (intermittent) vibration of the fuel assembly takes place, which is also detected by the neutron detector.

The methods used to detect impacting can be divided into two categories: traditional or spectral analysis-based methods, utilizing the stationary part of the signal, and transient analysis methods, utilizing the intermittent part of the signal. These latter methods are based on time-frequency analysis methods, such as short-term Fourier transform, wavelet analysis, and wavelet filtering. These methods will not be discussed here. The methods based on traditional signal analysis are more subjective and intuitive, and they are not absolute. The main difficulty is not the detection of the vibrations themselves, since this can be done with a spectral analysis similar to that made in the core-barrel vibration analysis; rather, to find out when impacting starts to occur. Namely, the spectral properties change only very mildly when impacting occurs, compared to the impacting-free cases.

It turns out that the most effective way of discovering strong vibrations and suspecting impacting is to use, in addition to the analysis of the peaks in the detector APSD, also the fact that there is a rather characteristic pattern of phase and coherence behavior in detectors in the same string in a BWR in the impact-free case. The observation is that this pattern changes appreciably in a characteristic way when vibrations occur, and the severity of the vibrations can also be qualitatively extracted, giving an estimate of the likelihood of impacting.

The principles of the impact-free structure of the detector spectra were explained earlier in ► Subsect. 4.1.3. In the absence of vibrations, the APSD (auto-spectrum) of the LPRMs, that is, the individual detectors, is a smooth function of the frequency, and the coherence and phase between any two detectors in the same string follow a pattern characteristic for propagating perturbations in the presence of a local noise component (in-core BWR noise). The phase is linear up to 10 Hz, and the coherence shows a periodic peak-sink structure, whose maxima and minima coincide with the zero- and π -crossings of the phase. Such a case is shown in ► Fig. 16.

When the detector string starts to vibrate strongly, the linear phase, and to a lesser extent also the sink structure of the coherence, gets distorted with increasing vibrations. Since the lateral vibration occurs synchronously for all four detectors, the vibrations appear as strong “global” (in-phase) components in all detector signals. Thus, over the frequency range of vibrations, the phase will tend to zero instead of being a linear function with a nonzero slope. At the same time, the sink and peak structure of the coherence, which was discussed earlier, is also changed compared to the vibration-free case (the maxima and minima do not coincide with the zero- and π -crossings of the phase). The detector signals of an excessively vibrating detector tube are given in  Fig. 27 as an illustrative example. Compared to  Fig. 16, one can clearly conclude from the measured signals that the detector string was excessively vibrating. The most visible is the distortion of the phase around the vibration frequency; with increasing strength of the vibrations, the phase tends to be zero over an increasing frequency region around the vibration frequency, owing to the simultaneous movement of the two detectors. The case shown in  Fig. 27 indicates a large likelihood of impacting, which was confirmed through visible damage to the detector and the surrounding fuel assemblies after the cycle, during refueling.

More details on this particular case and on the method in general can be found in Pázsit and Glöckler (1994). This method has been used routinely in several Swedish power plants for diagnosing detector tube impacting.

5 Special Noise Techniques: Determination of Core Global Dynamical Parameters

In this subsection, the use of noise analysis for determining core global dynamical parameters is discussed. Such determinations are carried out without disturbing reactor operation and thus represent a unique opportunity to monitor some of the most important safety parameters of nuclear reactors on-line. Two applications are dealt with hereafter: the determination of the decay ratio (DR) in BWRs and the determination of the moderator temperature coefficient of reactivity (MTC) in PWRs.

5.1 Determination of the Decay Ratio in BWRs

The instability of BWRs, which is manifested by self-sustained power oscillations in the core, has been observed at the very early days of reactor operation, and the possibility of BWR instability was predicted by Thie (1959). Such instabilities are usually encountered during start-up conditions, that is, at reduced core flow and relatively high-power level. Calculations are thus performed via adequate coupled neutronic/thermal-hydraulic codes to verify under which conditions the reactor becomes unstable. This defines an exclusion zone, that is, a set of operating conditions on the power-flow map, which the reactor operator should always avoid. During the start-up tests of the reactor, measurements of the in-core neutron noise are usually performed. The goal of these measurements is to verify that there is a good agreement with the calculations.

Monitoring the stability with measurements, as well as determining the margins to instability requires the existence of a reliable quantitative stability indicator. Such a parameter should be an integral, global parameter of the core, similar to the reactivity. However, as will be clear from the discussion below, the situation is more involved because, unlike with the definition of the

■ Figure 27

Abnormal phase and coherence between detectors in an impacting detector string of a BWR

reactivity, the stability cannot be characterized only with quantities belonging to the fundamental eigenvalue and fundamental eigenmode. Also, there are several possibilities for choosing a stability parameter, of which we will only discuss the most common one, the decay ratio.

BWR instability is an intriguing subject far from being fully understood, and accordingly it has a vast literature (for a review see D'Auria et al. (1997)). To illustrate the point we list here a number of references, still far from being complete, to give a flavor of the diversity and vibrant character of the research in the field: van der Hagen et al. (1994), Takeuchi et al. (1994), Hennig (1999), Hotta et al. (1997), Oguma (1997), Verdú et al. (1998); Kitamura et al. (1999), Miro et al. (2000), Ginestar et al. (1992), Munoz-Cobo et al. (2004), Demazière and Pázsit (2005), and Zinzani et al. (2008).

We note here also that in this section we only consider stability analysis in the linear regime. As already mentioned, fully developed unstable oscillations are nonlinear and ways of characterizing and understanding nonlinear aspects and developing nonlinear diagnostics methods is under strong development (March-Leuba et al. 1983, 1984, 1986a, b; Cacuci et al. 1986; Cacuci 1993; Ginestar et al. 2006; Konno et al. 1999).

5.1.1 Stability Indicator

The most commonly used stability indicator is the so-called decay ratio (DR). One of the basic assumptions in the use of the DR is that the system dynamics can be modeled by a second-order oscillator, that is, any fluctuation $\delta\Psi(t)$ related to BWR instabilities obeys the following equation:

$$\delta\ddot{\Psi}(t) + 2\xi\omega_0\delta\dot{\Psi}(t) + \omega_0^2\delta\Psi(t) = f(t) \quad (276)$$

where $f(t)$ represents the driving force of the oscillation, usually assumed to be a white noise, ω_0 is the resonance frequency, and ξ characterizes the damping of the system. The general solution to this equation is given by

$$\delta\Psi(t) = A \exp(-\xi\omega_0 t) \cos\left[\omega_0 \left(\sqrt{1-\xi^2}\right) t + \varphi\right] \quad (277)$$

The DR gives a measurement of the damping of the system and is defined as the ratio between two consecutive maxima of the signal form given above and found to be given, in the case of a second-order system, as

$$DR = \exp\left(\frac{-2\pi\xi}{\sqrt{1-\xi^2}}\right) \quad (278)$$

In practice, it is not the signal itself, but the auto-correlation function (ACF) of the normalized neutron density, or alternatively the impulse response function (IRF) as calculated by using an autoregressive moving-average (ARMA) or an autoregressive model (AR) that are used. In case of a white noise driving force, these functions all have the same oscillatory and decaying properties as the deterministic solution (277). Hence, the DR is usually determined from the ratio between two consecutive maxima A_i and A_{i+1} of any of these two functions. The ACF and IRF obtained in the case of a second-order system are represented in  Fig. 28. The DR

■ Figure 28

Auto-correlation function (ACF) and impulse response function (IRF) of a second-order system (on the left and right-hand sides, respectively)

gives therefore a measure of the inherent damping properties of the system. Using each detector separately allows estimating the decay ratio (DR) according to the following standard method (for a review, see D'Auria et al. 1997)

$$DR = \frac{A_{i+1}}{A_i}, \quad \forall i \quad (279)$$

If the dynamics of the system does not correspond to a pure second-order system, the above formula gives different results depending on which consecutive peaks of the ACF or of the IRF one considers.

5.1.2 Stability Mechanism of a BWR

Nuclear reactors must be designed such that they have a negative feedback mechanism, that is, any perturbation leading to off-normal conditions should be counteracted by some feedback, which thus brings the system back to steady-state conditions. Instabilities can arise from the fact that in a dynamic case, such feedback mechanisms act with some time delay. If the feedback was always exactly counteracting the original perturbation without time delay, the phase shift between the perturbation and the feedback should be -180° (i.e., out-of-phase). Nevertheless, in most cases, the phase shift differs from -180° . As a result, the feedback reinforces the original perturbation instead of damping it during some parts of a period.

Several physical mechanisms are responsible for the feedback in a BWR. The ones that might give rise to instabilities are the channel thermal-hydraulics (density wave oscillation, DWO) and the void-reactivity feedback. In the following, these two mechanisms are detailed. How these processes are driving instabilities will be explained in the next subsection.

A DWO corresponds to a change of the density of the coolant within one or several fuel assemblies. For illustration purposes, one can consider a perturbation induced by an inlet flow perturbation to a fuel assembly. Such an inlet perturbation will create a modification of the single-phase pressure drop in the single-phase region of the heated channel. This perturbation

will travel upward with the flow and will itself generate a modification of the two-phase pressure drop in the two-phase region of the heated channel.

The void-reactivity feedback comes from the fact that any modification of the density of the coolant affects the neutron moderation. More specifically, any decrease in the moderator density leads to a worsening of the neutron moderation. Such an effect is typically represented by the void coefficient of reactivity, that is,

$$\alpha_v = \frac{\partial \rho}{\partial v} \quad (280)$$

where $\delta \rho$ represents the change of reactivity of the system due to a change δv of the void fraction, with the void fraction being defined as the relative volume of vapor contained in a specific volume. Such a reactivity coefficient is strongly negative for BWRs.

Any perturbation of the reactivity of the system will lead to a perturbation of the reactor power and of the produced heat, which in turn will create a modification of the fuel temperature and of the void fraction. Because of the Doppler fuel temperature effect and of the void-reactivity feedback, such perturbations will affect the reactivity of the system. This feedback loop is called the direct loop. Further, a so-called recirculation loop is connected to the downcomer of a BWR. Such a loop has its own dynamical properties. As a consequence, any perturbation of the core outlet pressure will give rise to perturbation of the core-inlet flow via the recirculation loop dynamics. Such a feedback loop is called the indirect loop. Finally, each fuel channel has its own dynamical properties from a thermal-hydraulic point of view. Any perturbation to the channel thermal-hydraulics will give rise to DWOs, and this corresponds to the so-called DWO loop in the stability mechanism of a BWR.

5.1.3 Types of BWR Instabilities

Three types of instabilities are usually encountered in forced-circulation BWRs: pure DWOs or local oscillations, global (or in-phase) oscillations, and regional (or out-of-phase) oscillations. Whereas the global and regional oscillations also involve DWOs in the core, the instabilities are driven by the void-reactivity feedback, as will be explained in the following.

Instabilities due to pure DWOs might occur when the boundary conditions of the heated channel(s) are imposed, as is the case for the pressure drop between the inlet and outlet of the channels. Such instabilities are usually referred to as pure DWO or local oscillations. Due to this imposed boundary condition, the two-phase pressure drop in the perturbed fuel channel will create a feedback pressure perturbation of the opposite sign in the single-phase region, either reinforcing or damping the initial perturbation (see Yadigaroglu and Bergles 1972). This pressure drop oscillation can also be translated into a perturbation of the coolant density (explaining the name of DWO for this kind of perturbation). The typical frequency at which such oscillations are encountered is around 0.5 Hz, which is related to the transit time of perturbations from the inlet to the outlet of the fuel assemblies. This type of oscillation typically occurs when a fuel assembly is unseated, that is, does not sit properly of the lower fuel tie plate of the core (such a case was described in ► Sect. 4.1.1). Since each fuel assembly in a BWR is contained in a fuel box, the fuel channels are independent from each other. Therefore, in case of an unseated fuel assembly, some of the coolant bypasses the fuel channel. This reduces the single-phase pressure drop at the inlet of the channel, and destabilizes it. Radially, this perturbation is equivalent to

■ Figure 29

Space-dependence of the neutron noise induced by a local oscillation as calculated by the neutron noise simulator

a local noise source, or a so-called absorber of variable strength-type of noise source and can be modeled by the neutron noise simulator described in 🔍 Sect. 3.3.3 (Demazière 2004). An example of the results of such a modeling is shown in 🔍 Fig. 29. The induced neutron noise has thus its largest amplitude at the position of the noise source, and has a fast spatial decay away from it.

Instabilities due to the void-reactivity feedback may also occur in a BWR. The mechanism driving this kind of oscillation is mainly the time delay between a given power perturbation and the corresponding reactivity response due to the void/pressure coefficient. In some cases, the initial perturbation can be reinforced by the void/pressure feedback if the phase of this delayed response coincides with the phase of the power perturbation. It has to be emphasized that these instabilities also involve density waves through the core, but such waves alone are not responsible for the oscillations. Two types of instabilities involving such a coupling between the neutron kinetics and the thermal-hydraulics are usually encountered: in-phase (or global) oscillations, and out-of-phase (or regional) oscillations. In order to better understand the spatial dependence of such oscillations, the neutron flux can be expanded on the eigenfunctions of the system as

$$\phi(\mathbf{r}, t) = \sum_n a_n(t) \phi_n(\mathbf{r}) \quad (281)$$

where $\phi_n(\mathbf{r})$ represents the eigenfunction of the system of order n . For the sake of simplicity, assuming one group of delayed neutrons, a homogeneous reactor, and one-group diffusion theory, one could demonstrate that (the interested reader is referred to Lamarsh (2002) for the derivation of the following equations)

$$a_n(t) = A_n \exp(\omega_n t) \quad (282)$$

where A_n is a constant, and ω_n fulfills the following “in-hour” equation:

$$\rho_n = \frac{\omega t_n}{1 + \omega t_n} + \frac{\omega}{1 + \omega t_n} \cdot \frac{\beta}{\omega + \lambda} \quad (283)$$

with

$$t_n = \frac{1}{v(\Sigma_a + B_n^2 D)} \quad (284)$$

and B_n^2 is the geometrical buckling corresponding to the eigenmode n . One can easily show that

$$\omega_1 < \omega_0 \quad (285)$$

$$\dots \omega_2 < \omega_1 < 0 \quad (286)$$

and ω_0 is the only of the ω_n that can be positive.

For the global (in-phase) oscillation, the flux is oscillating over the whole core at a typical frequency of 0.5 Hz, and only the first neutronic mode (fundamental mode), that is, $n = 0$, is excited. This is explained by the fact that the reactivity ρ_0 of the fundamental mode is the only one that can be larger than zero and correspondingly ω_0 can be positive. The space-dependence of the flux is thus following the first neutronic mode. Due to the global character of the perturbation, the flow oscillations induced by the void/pressure oscillations are damped by the friction in the recirculation loop, and the recirculation loop dynamics has a stabilizing effect. The neutron noise induced by such an instability can be modeled by the neutron noise simulator, since the different eigenfunctions can be estimated by this tool. An example of the results of such a modeling is presented in ► Fig. 30.

For the out-of-phase (regional) oscillation, the second and third neutronic mode (first and second azimuthal modes), that is, $n = 1$ and 2, are excited. Such modes are subcritical and should decay in time in an exponential manner. Nevertheless, the excitation of such modes leads to positive flow rate perturbations in one half of the core counterbalanced by negative flow rate perturbations in the other half of the core at any time in such a way that the boundary conditions imposed by the recirculation loop are always fulfilled. As a consequence, such oscillations are self-sustained by the thermal-hydraulics. The neutron noise induced by such an instability can also be modeled by the neutron noise simulator. An example of the results of such a modeling is presented in ► Fig. 31. One characteristic of the regional oscillation is that several higher modes can be excited, compared to only one for the in-phase oscillation. Typically, the second and third modes, that is, first and second azimuthal modes, respectively, are excited. Even if these modes are subcritical, the thermal-hydraulics might self-sustain the oscillations. The oscillation frequency of these two modes, although typically close to 0.5 Hz, might be slightly different from each other. Thus, the resulting oscillation, which is the sum of these two modes, might exhibit a rotating neutral line, with the neutral line being defined as the line separating the positive

■ Figure 30

Space-dependence of the neutron noise induced by a global oscillation as calculated by the neutron noise simulator (on the left-hand side) and conceptual illustration of the in-phase behavior of the flow and power oscillations (on the right-hand side) (From Shiralkar, 2005)

and the negative lobes of the oscillation. An equivalent formulation is to say that there exists a phase shift between the first and second azimuthal modes, and that this phase shift is time-dependent, as illustrated in ► Fig. 32. Very often, a fourth mode, that is, the first axial mode, can also be excited. The regional or out-of-phase oscillation is thus a complicated oscillation due to its spatial intermittence, that is, the neutral line might be stable or it might rotate.

5.1.4 Combined Types of Oscillations

When instability events occur at nuclear power plants, several types of oscillations are usually excited simultaneously, even if typically only one is predominant. This complicates significantly the estimation of the DR, since as explained earlier, the DR is based on the assumption that only one type of oscillation exists. Furthermore, it is customary to estimate the DR from the LPRMs, that is, a value of the DR is estimated for each LPRM. One direct consequence of using local measurements for estimating a global parameter such as the DR is that the estimations might exhibit a space-dependence.

If only one mode type of oscillation is excited, then the DR is the same throughout the core. If several types are excited, the DR might become space-dependent. This can be demonstrated by assuming that the oscillations of the neutron flux can be written as a sum of the contributions of two oscillating modes, due to two different noise sources i ($i = 1, 2$), each of them being factorized into a temporal part only and spatial part only ($\varphi_i(\mathbf{r})$). In such a case, the DR, defined

■ Figure 31

Space-dependence of the neutron noise induced by a regional oscillation as calculated by the neutron noise simulator (on the left-hand side) and conceptual illustration of the out-of-phase behavior of the flow and power oscillations (on the right-hand side) (From Shiralkar, 2005)

as the ratio of the first and the second maxima of the ACF, is given by (Pázsit 1995)

$$DR(\mathbf{r}) = \sum_{i=1}^2 c_i(\mathbf{r}) \cdot DR_i \quad (287)$$

with

$$c_i(\mathbf{r}) = \frac{1}{1 + C \cdot \frac{\varphi_j(\mathbf{r})}{\varphi_i(\mathbf{r})} \cdot \frac{\ell n(DR_i)}{\ell n(DR_j)}}, \quad i \neq j \quad (288)$$

This expression was obtained assuming that each oscillation mode i has the same resonance frequency but different stability properties, that is, DRs. Furthermore, it was supposed that the CPSD between the two noise sources is negligible, and that the DR of any of the two noise sources was larger than 0.4. $\varphi_i(\mathbf{r})$ represents the radial space-dependence of the neutron noise induced by the noise source i . This spatial dependence can be estimated by the neutron noise simulator for all types of BWR instabilities (global, regional, or local oscillations). The coefficient C represents the ratio between the strength of the noise sources and is a normalization coefficient. The DR exhibits a strong radial space-dependence only when there are at least two types or sources of instabilities in the core with different stability properties, and at least one of those correspond to a local oscillation.

■ Figure 32

Definition of the time-dependent phase shift $\varphi(t)$ between the first and second azimuthal modes

■ Figure 33

Simulated radial space-dependence of the decay ratio (DR) in case of a local noise source and a global noise source (the white square represents the location of the local noise source)

The case of a local oscillation coexisting with a global oscillation is shown in ► Fig. 33. The reason of the sharp boundary between the two stability regions when at least one local noise source exists is the fast spatial decay of the amplitude of the local oscillations. Such a pattern for the spatial dependence of the DR was actually noticed at the Forsmark-1 BWR, as can be seen in ► Fig. 34, during the channel instability event already mentioned in ► Sects. 4.1.1 and ► 5.1.3 (the interested reader is referred to Oguma 1997). Equations (287) and (288) allow explaining the space-dependence of the DR in the Forsmark case, since a local oscillation could be triggered by an unseated fuel assembly.

In order to correctly estimate the stability properties of a BWR, it is thus essential to separate the different types of oscillations from each other. Thereafter, the stability of each mode can be characterized by a DR per oscillation mode. Different techniques have been elaborated for monitoring the stability of BWRs and for separating the different modes of oscillations.

While the global oscillations can be properly detected by the average-power range monitors (APRMs), the LPRMs are necessary to characterize the regional oscillations. The monitoring techniques that are capable of detecting different types of oscillations can basically be classified into three categories, which are briefly explained in the following in increasing order of sophistication.

The first class of techniques aims at monitoring the phase difference between pairs of symmetrically located LPRM detectors. A phase shift approaching 180° indicates out-of-phase oscillations, whereas a negligible phase shift indicates in-phase oscillations. The drawback of these techniques is the difficulty in monitoring combined modes of oscillations.

■ Figure 34

Radial space-dependence of the DR determined at the Forsmark-1 BWR during the 1996/1997 channel instability (Derived from Oguma, 1997)

The second category of techniques is based on the determination of the part of the LPRM signals related to the in-phase oscillations, using for instance the property of orthogonality between the fluctuations of the shape function of the neutron noise and the static flux (see (191) and (192)). This leads to

$$\frac{\delta P(t)}{P_0} = \frac{\delta \phi^{pk}(\mathbf{r}, t)}{\phi_0(\mathbf{r})} = \frac{\int \delta \phi(\mathbf{r}, t) \phi_0(\mathbf{r}) d\mathbf{r}}{\int \phi_0^2(\mathbf{r}) d\mathbf{r}} \quad (289)$$

Subtracting this in-phase component to each of the LPRM signals also allows detecting possible out-of-phase oscillations.

The last class of techniques is based on modal decomposition of the neutron noise. In this procedure, the neutron flux is expanded in the eigenfunctions of the system as

$$\vec{\phi}(t) = \sum_n a_n(t) \vec{\phi}_n \quad (290)$$

with

$$a_n(t) = \frac{\langle \vec{\phi}_n^\dagger, \vec{F} \times \vec{\phi}(t) \rangle}{\langle \vec{\phi}_n^\dagger, \vec{F} \times \vec{\phi}_n \rangle} \quad (291)$$

■ Figure 35

Time-dependence of the expansion coefficients for the three first modes applied to the local power range monitor (LPRM) signals during a stability test at the Ringhals-1 BWR

In these equations, the vector $\vec{\phi}(t)$ represents the space- and time-dependent neutron flux (where each element of the vector represents the value of the time-dependent flux at a spatial point in the system), $\vec{\phi}_n$ represents the space-dependent eigenfunction of mode n , $\vec{\phi}_n^\dagger$ is its adjoint, and $\bar{F}$ is the fission operator. This decomposition can be performed either with the prior determination of the different modes of the static neutron flux or without it. An example of such a modal decomposition applied to a stability test performed at the Swedish Ringhals-1 BWR is represented in [Fig. 35](#). As can be seen in this figure, both the global and the regional oscillation patterns are excited in the analyzed stability test. It is interesting to notice that both the global and regional oscillations are clearly intermittent, and that they sometimes exhibit growing amplitudes over a couple of periods. Furthermore, it can also be seen that the phase shift between the first and second azimuthal modes is varying with time. As a consequence, the regional oscillation, which is a combination of these two azimuthal modes, will be characterized by a rotating neutral (nodal) line.

5.2 Determination of the Moderator Temperature Coefficient of Reactivity in PWRs

5.2.1 Definition of the MTC

According to the newest American Standard, the MTC is defined as the partial derivative of the reactivity ρ with respect to the core-averaged moderator temperature T_m^{ave} as follows:

$$MTC = \frac{\partial \rho}{\partial T_m^{ave}} \quad (292)$$

For a small change in the average moderator temperature, the reactivity change would be

$$\delta\rho(t) = MTC \times \delta T_m^{ave}(t) \quad (293)$$

where the core-averaged moderator temperature change is defined using a proper weighting function $w(r)$ as

$$\delta T_m^{ave}(t) = \frac{\int \delta T_m(r, t) w(r) dr}{\int w(r) dr} \quad (294)$$

The determination of the weighting function will be discussed later on.

The fact that the temperature coefficient is defined through a partial derivative means that the MTC only accounts for changes in reactivity when the temperature of the coolant is changed, but the fuel temperature does not change. Therefore, in the traditional way of measuring the MTC by the so-called boron dilution method, when the temperature of the core is raised in an adiabatic manner and the excess reactivity to keep the core critical by diluting the boron content, the contributions to the reactivity change by changed fuel temperature, through the Doppler coefficient, has to be subtracted by calculations. Hence, the traditional method is both costly and is not a pure experimental method, rather a combination of calculations and measurement.

5.2.2 Derivation of the MTC Noise Estimate

It is therefore attractive to elaborate a noise-based method, which does not interfere with the operation and which is capable to measure the true MTC without corrections based on calculations. This can be achieved with a cross-correlation between the reactivity noise, deduced from neutron noise measurements, and from measurement of the temperature noise in the core or at the core exit. Such measurements can be performed with the required accuracy since temperature measurements have a large absolute accuracy, whereas from the neutron detectors only a normalized (by the mean value) signal is needed.

The starting point of consideration is as follows. If the reactivity depends on the stationary ergodic processes $s_i(t)$, $i = 1, \dots, N$, expanding the reactivity variation around the stationary value and assuming linear theory will lead to

$$\delta\rho(t) \approx MTC \times \delta T_m^{ave}(t) + \sum_{i=1, s_i \neq T_m^{ave}}^N \frac{\partial \rho}{\partial s_i} \times \delta s_i(t) \quad (295)$$

in which the MTC effect is separated from the other effects. In (295), all the time-dependent parameters are defined as their variations compared to the mean values.

The idea of using noise analysis to monitor the MTC in PWRs was probably first introduced by Thie in 1977, who suggested to use the root-mean-square values of the temperature noise and of the reactivity noise, which can be determined from the relative neutron noise under some assumptions, to evaluate the MTC:

$$MTC = \frac{\sigma_{\delta\rho}}{\sigma_{\delta T_m^{ave}}} \quad (296)$$

From (295), one can see that the MTC evaluated by (296) is biased due to the contamination of the neutron noise from noise sources other than the moderator temperature noise.

Later Pór et al. (1985) suggested that the contribution of the other noise sources can be removed if spectral analysis of the signals is used, as explained in the following. Multiplying (295) by $T_m^{ave}(t + \tau)$ and taking the average gives

$$CCF_{\delta\rho, \delta T_m^{ave}}(\tau) = MTC \times ACF_{\delta s_i, T_m^{ave}}(\tau) + \sum_{i=1, s_i \neq T_m^{ave}}^N \frac{\partial \rho}{\partial s_i} \times CCF_{\delta s_i, \delta T_m^{ave}}(\tau) \quad (297)$$

where ACF and CCF stand for the auto-correlation function and the cross-correlation function, respectively:

$$CCF_{\delta\rho, \delta T_m^{ave}}(\tau) = \langle \delta\rho(t) \delta T_m^{ave}(t + \tau) \rangle \quad (298)$$

$$CCF_{\delta s_i, \delta T_m^{ave}}(\tau) = \langle \delta s_i(t) \delta T_m^{ave}(t + \tau) \rangle \quad (299)$$

$$ACF_{\delta T_m^{ave}}(\tau) = \langle \delta T_m^{ave}(t) \delta T_m^{ave}(t + \tau) \rangle \quad (300)$$

If it can be assumed that the fluctuations of the different s_i parameters ($s_i \neq T_m^{ave}$) are statistically independent of moderator temperature fluctuations, then their cross-correlation vanishes

$$CCF_{\delta s_i, \delta T_m^{ave}}(\tau) = 0 \quad (301)$$

It can be shown that this assumption is valid within a certain frequency region. Then one has

$$MTC = \frac{CCF_{\delta\rho, \delta T_m^{ave}}(\tau)}{ACF_{\delta T_m^{ave}}(\tau)} \quad (302)$$

Alternatively, the MTC can also be derived by multiplying (295) by $\delta\rho(t + \tau)$ and taking the average

$$MTC = \frac{ACF_{\delta\rho}(\tau)}{CCF_{\delta T_m^{ave}, \delta\rho}(\tau)} \quad (303)$$

Equation (302) or (303) represents the MTC noise estimator that should be used in noise analysis in order to get the correct value of the MTC.

5.2.3 Measurement by Noise Analysis Technique

Although (302) and (303) are written in the time domain, it is much more common (and practical) to perform the MTC estimation in the frequency domain. This reads as

$$MTC = \frac{CPSD_{\delta\rho, \delta T_m^{ave}}(\omega)}{APSD_{\delta T_m^{ave}}(\omega)} \quad (304)$$

or

$$MTC = \frac{APSD_{\delta\rho}(\omega)}{CPSD_{\delta T_m^{ave}, \delta\rho}(\omega)} \quad (305)$$

where the APSD and CPSD stand for the auto-power spectral density and cross-power spectral density, respectively.

Nevertheless, neither the at-power reactivity noise nor the average coolant temperature noise can be measured in practice in PWRs. Only the neutron flux (either via the ex-core neutron detectors or via the in-core neutron detectors, when they are present in the core) and the core-inlet/outlet temperatures are measurable quantities in PWRs. Simply speaking, the MTC should be estimated by using global parameters, such as the reactivity and the average moderator temperature, whereas only local quantities (flux and temperature) can be measured.

The reactivity noise can, under some assumptions, be inferred from the flux noise, as explained in [Sect. 3.3.2](#). Namely, the flux noise in the frequency domain can be approximated by (second-order terms neglected)

$$\delta\phi(\mathbf{r}, \omega) = \delta\phi^{pk}(\mathbf{r}, \omega) + \delta\Psi(\mathbf{r}, \omega), \quad (306)$$

where

$$\delta\phi^{pk}(\mathbf{r}, \omega) = \phi_0(\mathbf{r}) \frac{\delta P(\omega)}{P_0} \quad (307)$$

is the point-kinetic component of the flux noise. The amplitude function itself satisfies the point-kinetic equations that can be written in the frequency domain

$$\frac{\delta P(\omega)}{P_0} = \delta\rho(\omega) G_0(\omega) \quad (308)$$

In this equation, $G_0(\omega)$ is the usual zero power reactor transfer function, in which no feedback effects between the reactor power and the coolant temperature, or between the reactor power and reactivity, are accounted for. Due to the relatively large time constant of the heat transfer dynamics from fuel to coolant, feedback effects will only occur at low frequencies, typically below 0.1 Hz. [Equation \(308\)](#) is therefore valid for frequencies higher than about 0.1 Hz. Hence one has

$$\delta\rho(\omega) = \frac{1}{G_0(\omega)} \frac{\delta\phi^{pk}(\mathbf{r}, \omega)}{\phi_0(\mathbf{r})} \quad (309)$$

In-core neutron detectors do not measure solely the point-kinetic component of the neutron noise, but the total flux noise, as defined by [\(306\)](#). Consequently, the reactivity noise can be calculated from the flux noise only if $\delta\phi^{pk}(\mathbf{r}, \omega)$ is overwhelmingly large compared to $\delta\Psi(\mathbf{r}, \omega)$, that is, the reactor behaves in a point-kinetic way. As was shown in previous parts of this section, large power reactors do not respond to localized perturbations in a point-kinetic way. However, the response of the core to distributed perturbations is much more point-kinetic-like, even if the perturbations in the different spatial points are loosely coupled to each other (which is the case of temperature fluctuations over a radial cross section of the core, due to loose thermohydraulic

coupling between the fuel channels). This was proven in simulations using the noise simulator. Hence, the approximation of the reactivity noise from a single in-core neutron detector is a permissible one:

$$\delta\rho^{approx}(\mathbf{r}, \omega) = \frac{1}{G_0(\omega)} \frac{\delta\phi(\mathbf{r}, \omega)}{\phi_0(\mathbf{r})} \cong \delta\rho(\mathbf{r}, \omega) \quad (310)$$

Regarding the temperature noise, only the local temperature noise can be measured in a PWR, usually at the top of only a few fuel assemblies. For a long time, in the noise-based method of determining the MTC, only a single core-exit thermocouple was used, whereas there is no reason to believe that the moderator temperature noise is homogeneous in the core:

$$\delta T_m(\mathbf{r}, \omega) \neq \delta T_m^{ave}(\omega) = \frac{\int \delta T_m(\mathbf{r}, \omega) w(\mathbf{r}) d\mathbf{r}}{\int w(\mathbf{r}) d\mathbf{r}} \quad (311)$$

Another, final problem is represented by the separation distance between the in-core neutron detector and the core-exit thermocouple, used in the measurement. The MTC can only be accurately determined if no temperature noise is generated between the neutron and the temperature detectors. Furthermore, due to the time constant of the detectors, the overwhelmingly large background noise at high frequencies, and the separation distance between the two detectors, the moderator temperature noise recorded by the core-exit thermocouple is damped, compared with the one recorded by the in-core neutron detector. There is nevertheless a large enough coherence for frequencies lower than 1 Hz between two in-core thermocouples located within the same fuel assembly to prove that the axial damping is not crucial for such frequencies.

Consequently, the MTC has to be evaluated using frequencies smaller than 1 Hz (because of the temperature noise), and frequencies larger than 0.1 Hz (because of the unknown closed-loop reactor transfer function that has to be replaced by the known open-loop reactor transfer function). Another advantage of using the frequency band 0.1–1.0 Hz is that the open-loop transfer function, as demonstrated in ► Sect. 3.3.2, equation (198) further simplifies into

$$G_0(\omega) \approx G_0^{plateau} = \frac{1}{\beta}, \quad (312)$$

which is called the plateau approximation.

Hence, the traditional MTC noise estimator that can be used in practice in the frequency range 0.1 to 1.0 Hz is defined as the H_1^{biased} estimator:

$$H_1^{biased}(\mathbf{r}, \omega) = \frac{1}{G_0(\omega)} \frac{CPSD_{\delta\phi/\phi_0, \delta T_m}(\mathbf{r}, \omega)}{APSD_{\delta T_m}(\mathbf{r}, \omega)} \quad (313)$$

or the H_2^{biased} estimator:

$$H_2^{biased}(\mathbf{r}, \omega) = \frac{1}{G_0(\omega)} \frac{APSD_{\delta\phi/\phi_0}(\mathbf{r}, \omega)}{CPSD_{\delta T_m, \delta\phi/\phi_0}(\mathbf{r}, \omega)} \quad (314)$$

depending on whether (304) or (305) is used.

The estimators (313) and (314) have been used numerous times in the past by several groups, but they did not have the expected accuracy. All results showed the same tendency: the MTC noise estimate was systematically underestimated by a factor of 2 to 5.

■ Figure 36

Maximum of the coherence between GT signals measured in Ringhals-2, cycle 24 (detectors located in the lower part of the core)

5.2.4 Elaboration of a Correct MTC Noise Estimator

The reason of the MTC underestimation by noise analysis was understood recently (Demazière 2004). Namely, the traditional noise estimator implicitly assumes that the moderator temperature noise is radially homogeneous in the core, and hence the measurement of the temperature fluctuations in one point is sufficient to estimate the driving force. However, if the temperature fluctuations are incoherent, such that they may be out-of-phase with each other at various radial points of the core, then the average temperature fluctuation is much smaller than the locally measured one, and the measurement based on the signal of a single thermocouple indeed severely underestimates the MTC.

This hypothesis was proven both in measurements and in calculations with the noise simulator. A noise measurement performed in the Swedish Ringhals-2 PWR during the fuel cycle 24 and summarized in ► Fig. 36 actually allowed mapping the radial distribution of the moderator temperature noise throughout the core via the use of gamma-thermometers (GTs), which as explained earlier, are working as ordinary thermocouples in the frequency range 0.1–1.0 Hz. It was then noticed that the moderator temperature noise was radially heterogeneous and loosely coupled.

In the simulations, spatially random temperature fluctuations with an exponentially decaying correlation were assumed as the driving source, and the neutronic response of the core was calculated with the noise simulator. The calculations proved that for such a distributed

perturbation the core response is very closely point kinetic, even if the correlation length of the perturbation is short, but for correlation lengths much smaller than the core diameter, the traditional MTC estimators significantly underestimate the true MTC.

A new MTC noise estimator, based on the radial average of the moderator temperature noise via the use of a proper weighting function, was thus derived to cope with the radially loosely coupled character of the temperature fluctuations (Demazière 2004). This new estimator assumes that the moderator temperature noise can be measured throughout the core, so that the core-averaged moderator noise can be evaluated according to (294). As a result, this new noise estimator is defined as

$$\tilde{H}_1^{\text{biased}}(\mathbf{r}, \omega) = \frac{1}{G_0(\omega)} \frac{\text{CPSD}_{\delta\phi/\phi_0, \delta T_m^{\text{ave}}}(\mathbf{r}, \omega)}{\text{APSD}_{\delta T_m^{\text{ave}}}(\omega)} \quad (315)$$

This new MTC noise estimator is still biased since, compared to the ideal MTC noise estimator given by (304), the total flux noise is used instead of its point-kinetic component for evaluating the reactivity noise. However, this bias is in general very small. The accuracy of the estimator (315) was also assessed and found rather satisfactory with the same tools, via the noise simulator and the earlier mentioned model of the temperature fluctuations, which were used to show the inaccuracy of the traditional method.

The new MTC noise estimator was tested at the Swedish Ringhals-2 PWR, where the gamma-thermometers (GTs) were used for mapping the moderator temperature noise throughout the core (► Fig. 37). Such evaluations are presented in ► Figs. 38 and ► 39 for two neutron detectors (neutron detector located in the fuel assembly L04 and in the fuel assembly H11, respectively). The MTC was also estimated using SIMULATE-3 and was found to be equal to $-51 \text{ pcm}/^\circ\text{C}$ for this core layout and burnup. In these figures, the points used for the final MTC evaluation are circled in bold and represent the frequencies for which the coherence between the neutron noise and the core-averaged moderator temperature noise is high enough to provide reliable MTC evaluations. In these estimations, the so-called w_2 weighting function was used to evaluate the core-averaged moderator temperature noise. Such a weighting function is defined as

$$w_2(\mathbf{r}) = \phi_0^2(\mathbf{r}) \quad (316)$$

since it can be proven using first-order perturbation theory (in one-group diffusion approximation) and assuming proportionality between the moderator temperature noise and the corresponding macroscopic cross section noise that the weighting function that needs to be used to evaluate the core-averaged moderator temperature noise should be equal to the square of the static flux. Furthermore, the w_2 weighting function uses the square of the mean value of the GT signals as neutron signals, since in static mode the GTs measure the gamma flux, which is proportional to the neutron flux.

The main conclusion from this MTC noise measurement is that using the new MTC noise estimator $\tilde{H}_1^{\text{biased}}$ gives an MTC value that is very close to the reference value, if one takes the confidence intervals into account. The fact that the results using the core average moderator temperature noise do not depend strongly on the radial position of the neutron detector used in the MTC evaluation and give the actual MTC value suggests that the deviation of the reactor response from point kinetics does not play a significant role on the MTC estimation by noise analysis.

■ Figure 37

Radial location of the detectors for the moderator temperature coefficient of reactivity (MTC) noise measurement in Ringhals-2, cycle 26 (GT and ND stand for gamma-thermometer and neutron detector, respectively)

■ Figure 38

MTC noise estimation using the new MTC noise estimator at Ringhals-2, cycle 26 (with the neutron noise measured in the H11 fuel assembly)

■ Figure 39

MTC noise estimation using the new MTC noise estimator at Ringhals-2, cycle 26 (with the neutron noise measured in the L04 fuel assembly)

The new MTC noise estimator was also proven to correctly estimate the actual value of the MTC in a subsequent measurement performed at the Ringhals-2 PWR, fuel cycle 27 (Demazière et al. 2003), as well as at the Paks-3 VVER in Hungary (Makai et al. 2007). As verified by the measurements and as predicted by the use of the neutron noise simulator, the new MTC noise estimator allows to accurately estimate the MTC. In the measurement performed at the Paks reactor, a correction for the Doppler effect had nevertheless to be applied, since the MTC evaluations were performed at rather low frequencies, that is, frequencies for which the fuel temperature feedback is of significance.

6 Conclusions and Open Issues

Neutron fluctuations in zero power systems and power reactors have been studied and used for diagnostics of nuclear systems for a long time. What regards zero power systems (branching processes in constant material), the basic theory has been elaborated many decades ago, but new application areas appeared that made it necessary to develop the theory further. One area is accelerator-driven systems (ADSs) where the source is nonstationary and non-Poissonian. In pulsed experiments, correlations may occur in the generation times of neutrons within a pulse. Advances have been made in the theoretical description of such processes, but the present experimental knowledge on the statistics of source neutrons in a pulse is not complete. The number distribution of spallation neutrons has been investigated, but the temporal correlations as well as the energy correlations of the source neutrons are not known. More experimental data are needed in these questions.

Particle fluctuations in a fusion plasma are, as a rule, not related to a branching process, and hence have not been considered in this context. However, the secondary generation of runaway electrons is a branching process (through collisions of energetic electrons with low-energy electrons), which opens an interesting new research area. Although energy conservation in the

individual collisions would keep the total energy in a cascade constant, leading to a sub-Poisson variance, energy is fed to the cascade continuously through the electric field, counteracting the conservation relation and hence leading to significant fluctuations.

It has also to be mentioned that in this chapter, we only considered temporal fluctuations of the neutron number in a static, deterministic material. A completely different type of fluctuations in particle transport arises when the multiplying material cannot be given deterministically, rather only through probability distributions. Similar to the case of a temporally randomly varying material, this is another case of a doubly stochastic process through the spatially random distributions of the reaction cross sections (Sanchez 1989; Sanchez and Pomraning 1991). Several of the planned advanced reactor types, pebble bed reactor, molten salt reactor (MSR), the supercritical water reactor (SCWR), the fluidized bed reactor, will have a spatially random composition due to the redistribution of the fuel and/or the moderator, and some fuel types, such as the MOX fuel and the fuel of a pebble bed reactor, are inherently random. The theoretical treatment of such problems is described in ► Chap. 5, “General Principles of Neutron Transport” of this Handbook by Prinja and Larsen.

In the safeguards field, the main challenge for the near future appears to be the treatment of the dead-time effect on the higher moments of the distribution of detected neutrons and photons (Degweker 1998, 1999; Croft and Bourva 2000). Recently, the dead-time problem has been only treated at the level of the first moment, whereas there are only empirical estimates or Monte Carlo simulation available to estimate the effect of dead-time on the higher moments (and hence the multiplicity detection rates). In addition, new measurement methods (coupled neutron-gamma statistics; novel uses of pulsed neutron generators) as well as new data processing methods (for unfolding of the highly nonlinear relations between the measured multiplicity rates and the searched sample parameters) are under elaboration.

In the field of power reactor diagnostics, there are challenges and open issues regarding the diagnostics of both present generation reactors as well as that of the next generation nuclear power plants. On the computational side, the emphasis was shifted from using simple models, in which analytical solutions can be obtained for the direct task, that is, an analytical expression for the noise induced by a model perturbation, to using numerical methods for the calculation of the noise in real heterogeneous systems. One significance of the analytical solution of the direct task was the potential possibility of devising an analytical, or at least algorithmic inversion procedure to express parameters of the noise source. However, in the meantime, powerful nonparametric inversion algorithms have been taken into use, such as artificial neural networks (ANN) and fuzzy logic systems. These only require a numerical training set, provided by numerical solution of the direct task, to be trained such that they can handle the inverse task.

What regards the development of such noise simulators that can be used to calculate the induced noise numerically in real heterogeneous systems, similarly to the static and dynamic safety calculations, the development points toward multi-physics calculations, that is, coupled core physics – thermal-hydraulics calculations, which take into account the feedback paths between fluid flow, heat transfer, and neutronics. Such simulators are able to handle the nonlinearity in the relevant processes.

Although, in a realistic case, such solutions can only be obtained by complete numerical simulations, the parallel work of understanding of nonlinear processes via simplified models remains an important task. The nonlinearity of the BWR instability and the use of nonlinear analysis methods for diagnostics and stability analysis of BWRs is a field under strong development.

Regarding the signal analysis part, in addition to nonlinearities, an increased attention is given to the fact that real systems, especially when they have nonlinear features, do not behave in a stationary manner. A prominent example is BWR oscillations in an unstable case, which behave clearly in an intermittent manner. It is important to both understand the physical reasons for intermittence and be able to extract maximum information from the nonstationary signals, which cannot be processed by traditional spectral analysis methods. Short-term Fourier transform and wavelet transform are two powerful methods, which started to be used for such analysis, and work is going on in this direction.

Turning into new reactors and new fuel constructions, they will raise new questions and there will be a need for developing both new core physics and diagnostic methods. Even the use of MOX fuel in Generation III and III+ reactors will pose new requests for diagnostics: it is anticipated that at the beginning of cycle the MTC will be allowed to be positive, although smaller than the Doppler effect and other negative reactivity coefficients, in order to avoid a too large negative MTC at the end of the fuel cycle. Monitoring of the MTC, and access to a reliable measurement method will gain importance.

Regarding Gen-IV reactors, and other advanced reactor concepts such as ADS, several of them have properties very much different from the reactors up to Gen-III+ (van Dam 2000; Lathouwers et al. 2003). This means that new types of anomalies may occur, necessitating new noise source models, and new methods of solving both the direct and the inverse task will be necessary to develop. In reactors, like in a subcritical ADS, or a core with circulating liquid fuel, new reactor theory is necessary even to define the kinetic approximations, the role and use of adjoint methods, etc.

Last, but not least, noise diagnostic methods used in fission reactors will be interesting to transfer to fusion reactors, as they approach more stable regimes of operation, and research in fusion and fission reactors might find synergy effects such as hybrid reactors. Such a work has already been started (Karlsson et al. 1997; Pokol et al. 2007). However, fusion plasma processes are highly nonstationary and nonlinear, which will push the development of such analysis methods further.

Acknowledgments

The first author (I.P.) is much indebted to many colleagues with whom he had a very useful and pleasant collaboration in the field of reactor diagnostics from which he benefited very much. He was introduced to the field by his PhD advisor, the late G. Kosály. Special thanks go to M.M.R. Williams of Queen Mary College and Imperial College, from whom he learnt immensely in all aspects of neutron fluctuations and reactor noise. H. van Dam is acknowledged for many enjoyable discussions and for his inspiration. The author's interest in neutron fluctuations in zero power systems stems from the pioneering work of L. Pál, his former professor and once the chairman of his PhD exam. He is privileged for the opportunity to start a joint work with L. Pál at a later stage, one result of which is a recent monograph they coauthored on neutron fluctuations. The first part of this chapter is largely based on their book.

The authors wish to thank Maria Pázsit for the typesetting of the second part of this chapter, which was originally prepared with a different word processor, without which this material would not have a chance to be ready in time.

Abstract: The main theme of this chapter is the process and evolution of deterministic and probabilistic safety analyses that have played a backbone role in assuring public health and safety in the peaceful uses of nuclear power. The chapter begins with a discussion of the origin of nuclear power safety analysis together with the overall perspectives of both deterministic and probabilistic approaches that are still prevalent, although there is an increasing trend in application of probabilistic safety analysis in safety-related decision making. Deterministic approaches, such as the defense-in-depth or safety margin, are regarded as a means to cope with uncertainties associated with adequacy of safety features. As probabilistic methods and applications gain maturity and acceptance, the uncertainties associated with safety features are measured and described probabilistically. The chapter concludes with a detailed discussion of the probabilistic safety assessment and its uses in nuclear power safety analysis.

1 Origin and Methodological Framework of Deterministic Safety Analysis

The safety analysis of nuclear power plants to protect public health and safety from radiation exposure hazards (The word “hazard” in this chapter mainly refers to exposure of workers and the public to radiation from a nuclear plant.) is largely deterministic, although methods of probabilistic safety assessment are being increasingly used. This section discusses the origin and methodological framework of the deterministic safety analysis.

1.1 Origin of Nuclear Power Safety and Regulation

1.1.1 First Implementation of Nuclear Safety in the USA

During the pioneering experiment of a controlled nuclear fission chain reaction at the University of Chicago in 1942, the concept of safety was first implemented by the scientists led by Enrico Fermi. Contemplating the possibility of a failure in the experimental facilities, they designed multiple safeguards into the experiment to prepare for the unknown.

The first safeguard consisted of two sets of safety control rods including an emergency safety rod that played a role of “Safety Control Rod Axe Man (scram)” to cope with the failure of another set. In addition, a cadmium-salt solution was also prepared as a sort of “liquid-control squad” to allow it to pour over the experiment in the case where all the mechanical safety features fail. In fact, these multiple safeguards represent an implementation of the so-called “defense-in-depth” (DID) philosophy design in designing safety features for nuclear plants, although this terminology was not established then.

1.1.2 Reactor Design Safety by Du Pont Engineers

The Manhattan Project in the USA during the World War II included several separate disciplines: experimental and theoretical physics, chemical engineering, mechanical engineering, and electrical engineering. Each group brought different methods of design and construction

to the project. The chemical engineers of the Du Pont Corporation led the effort to build several nuclear reactors in the town of Hanford in the state of Washington. Using their background in chemical processes, the Du Pont engineers broke the reactor design into smaller, relatively independent subsystems, whose design would be frozen early, so that any dependent system could be designed as well (Rhodes 1986).

This created the concept of functional and structural independence and later gave rise to a major safety philosophy extensively applied in nuclear power arena, i.e., “defense-in-depth.” Originating from military strategy, the defense-in-depth (DID) requires a defender deploy resources such as fortifications, field works, and military units at and well behind the front line, so as to slowdown the momentum of the attacker over a period of time rather than defeating an attacker with a single strong defense line. The same philosophy in the nuclear power system design promotes use of layers of redundant and diverse independent barriers (The word “barrier” in this chapter is used to refer to those structures, systems, components, and software and human interventions that can detect, prevent, protect, and mitigate radiation exposure hazards and consequences of such hazards.) to prevent and mitigate the likelihood of release of highly radioactive fission products into the environment.

Because the Du Pont engineers lacked a track record with the nuclear technology, they incorporated several safety features to overcome the uncertainties in characterizing the performance and effectiveness of the barriers including redundancy, diversity, large safety margins, and safety systems designed to limit the release of radioactive effluents, which would contaminate the environment.

1.1.3 US Atomic Energy Commission

Shortly following the World War II, there was significant interest in the peaceful uses of nuclear power and there arose the necessity of regulating nuclear power applications. Nuclear regulation was the responsibility of the US Atomic Energy Commission (AEC), a five-member Commission that the U S Congress established as part of the Atomic Energy Act of 1946 to maintain strict control over atomic technology and to exploit it further for military applications. The 1946 Act, passed while the USA–Soviet Union relationship was strained with the start of the Cold War, tacitly acknowledged the potential peaceful benefits of atomic power. It highlighted the military aspects of nuclear energy and the need for secrecy. The 1946 law excluded commercial applications of atomic energy and rested the ownership of the nuclear knowledge with the US government.

Influenced by President Eisenhower’s “Atom for Peace” initiative in 1953, the US Congress later replaced the 1946 Act with the Atomic Energy Act of 1954, which made the commercial development of nuclear power possible. The 1954 Act ended the government’s monopoly on technical data and made the need for commercial nuclear power an urgent national goal to promote the peaceful uses of atomic energy, provided a reasonable assurance that such uses would not result in undue risks to the health and safety of the public, exists. The 1954 Act directed the AEC “to encourage widespread participation in the development and utilization of atomic energy for peaceful purposes.”

At the same time, it required the AEC to regulate the anticipated nuclear industry to protect public health and safety from radiation hazards. The AEC’s fundamental objective in drafting regulations was to ensure that public health and safety were protected without imposing overly

burdensome requirements that would impede industrial growth (NUREG-BR-0175). However, the inherent difficulty the AEC faced in distinguishing between essential and excessive safety regulations was soon compounded by technical uncertainties and limited operating experience with power reactors. The technical and safety issues that arose during this period included the effect of radiation on the properties of reactor materials; the durability of steel and other metals under stress in a reactor; the ways in which water reacted with uranium, thorium, aluminum, and other elements in a reactor; and the measures needed to minimize radiation exposure in the event of a large accident.

1.1.4 International Atomic Energy Agency (IAEA)

In 1953, US President Dwight Eisenhower delivered a speech entitled “Atoms for Peace” before the United Nations General Assembly with a vision to create an international body to control and develop the use of atomic energy. The IAEA was subsequently created in 1957, with the following dual purposes, by a twelve-nation group: (1) promote the peaceful uses of nuclear energy, and (2) ensure that nuclear power would not be used to further any military purpose (Fischer 1997). The IAEA Statute completed at a 1957 conference contains three pillars of nuclear verification and security, safety, and technology transfer. In 1986, in response to the Chernobyl disaster, IAEA expanded its nuclear safety efforts.

Since 1974, the IAEA has provided a series of safety standards as well as international cooperation to ensure that high safety performance would be attained in all nuclear facilities of the member countries. The IAEA safety standards cover diverse areas of nuclear safety, radiation protection, radioactive waste management, the transport of radioactive materials, the safety of nuclear fuel cycle facilities, and quality assurance. For example, see <http://www-pub.iaea.org/mtcd/publications/publications.asp>. They are not regulations but recommendations. However, the basic principles set forth by these documents were well received by the member countries especially in developing safety regulations by the regulatory bodies.

1.2 Evolution of Methods for Safety Assurance

Over the past 60 years, the process of assuring safety has evolved into three ways of designing against accidents: rule-based, deterministic, and probabilistic methods. The last two look for identifying potential incidents and accident scenarios, which the designer must first try to *prevent* (i.e., avoid their occurrence). The designer must also provide *protection* against such scenarios (i.e., halt their progress) and finally provide *mitigation* (i.e., reduce their effects should they occur).

The rule-based approach prescribes specific design (or good practices) for selection of systems and components and requires maintaining them properly. This approach is not widely practiced in safety design and analysis of nuclear power plants, but is commonly used in designing reactor pressure vessels.

Deterministic analysis is largely experiential and requires the designer, regardless of the likelihood of such events and accident scenarios, to provide protection/mitigation for them. It uses conservative analysis techniques to assess adequacy and performance of safety systems designed to attain the DID objectives. The key terms “prevention,” “protection,” and “mitigation”

are also another way to express the “DID” design philosophy, which states simply that plant safety should not depend on only one physical barrier or system.

Probabilistic safety analysis, on the other hand, develops a big list of possible accident scenarios in a systematic way, and selects those exceeding certain criteria such as the yearly frequency of occurrence to identify and assess adequacy of safety-significant protection/mitigation features.

In the early safety assessments in the USA, due to the lack of information about the effectiveness and performance of the safety barriers, for avoiding the need to calculate best estimate uncertainties about the performance of nuclear plant safety features, safety engineers exclusively used deterministic analysis through conservative assumptions and calculations. They devised the concept of design basis accidents (DBAs) to measure the effectiveness of the physical barriers and safety systems. Safety was, therefore, defined as the ability of the nuclear reactor to withstand a fixed set of prescribed accident scenarios judged by the regulators as the most significant adverse events in a nuclear power plant that must be designed against. The premise was that if the plant can handle the DBAs, it could handle any other accidents – an attempt to eliminate the possibility of reactor failure from fundamental design flaws and worst possible accidents. Accordingly, accidents would be credible if their occurrence is caused by one single equipment failure or operational error following certain initiating events, with some considerations of the probability of such accidents. However, consideration of “incredible events” such as the catastrophic failure of the reactor pressure vessel or multiple independent failure events was excluded.

The Three Mile Island (TMI) accident (Kemeny et al. 1979; NSAC 1979; Rogovin and Framp-ton 1980) showed that the exclusion of multiple failures in assessing safety is not justified, and such events may happen and pose consequences worse than the DBAs. In particular, this lesson from the TMI accident gave rise to sustained use of probabilistic methods in safety and regulatory decisions as a means of identifying and evaluating accident scenarios involving multiple failures. The probabilistic methods are also increasingly used in most other countries as a means to support decision making to further enhance nuclear safety.

1.3 Defense-in-Depth

As noted earlier, DID is an element of the safety philosophy that employs successive compensatory measures to prevent accidents or mitigate damage if a malfunction or accident occurs at a nuclear facility (USNRC 1998). The DID philosophy ensures that safety will not be wholly dependent on any single element of the design, construction, maintenance, or operation of a nuclear facility. The net effect of incorporating DID into design, construction, maintenance, and operation is that the nuclear facility or system in question tends to be more resilient to failures and external challenges.

For example, consider the emergency core cooling system (ECCS) designed to protect the reactor core against the DBAs such as the large loss of coolant accident (LOCA). According to the DID design philosophy, the designers should first try to prevent such an accident, e.g., by designing the piping based on high quality standards with a means to detect leak before break. But, should it occur, there should be features available to prevent the reactor core from potential melting. If a melting occurs, the release of the radioactive inventories from the melted core outside of the reactor coolant system (RCS) or the containment should be prevented

or minimized. Finally, the design should have additional features to mitigate (minimize) any radioactive release to the environment.

Another very important, but subtle objective of the DID was to manage all sorts of uncertainties about the capabilities of safety features, the concept took the view that the nuclear regulation must apply it to design, construction, and operation to assure that normal operation, plant protection, radioisotope containment, and emergency preparedness goals were present, adequate (i.e., with large extra margins) and assured. This philosophy is discussed in IAEA document INSAG-10 (IAEA 1996), in terms of five levels of protection together with the essential means of achieving them in existing plants as shown in  [Table 1](#).

If one level of defense (i.e., a barrier) is not realized, the subsequent level is to be used, and so on. Clearly, of particular interest would be the hazards that could potentially degrade or fail several levels of defense, such as fire, flooding, or earthquakes (the so-called common mode failures). Human aspects of defense are also brought into play to protect the integrity of the barriers, such as quality assurance, administrative controls, safety reviews, operating limits, operating staff qualification and training, and safety culture.

Safety system designers should ensure to the extent achievable that the different safety systems act as or protect barriers against radioactive materials, and are functionally independent under the accident conditions such as the DBAs considered. Each physical barrier should be designed to meet its objectives conservatively, and its quality should be checked to ensure that the large margins against failure exist and are retained at all times. Severe accidents in the past have been invariably due to deficiencies in multiple components of the DID that should not have been permitted.

System design according to a conservative/deterministic approach to DID includes process control as well as feedback to withstand any failures, which might otherwise allow incipient faults or abnormal conditions to lead to accidents. These controls protect the physical barriers

 **Table 1**

Levels of defense-in-depth (DID) (IAEA 1996)

Levels of DID	Objective	Essential means
Level 1	Prevention of abnormal operation and failures	Conservative design and high quality in construction and operation
Level 2	Control of abnormal operation and detection of failures	Control, limiting and protection systems and other surveillance features
Level 3	Control of accidents within the design basis	Engineered safety features and accident procedures
Level 4	Control of severe plant conditions, including prevention of accident progression and mitigation of the consequences of severe accidents	Complementary measures and accident management
Level 5	Mitigation of radiological consequences of significant releases of radioactive materials	Off-site emergency response

by keeping the plant in a well defined region of operating parameters where barriers will not be jeopardized.

As a way to confirm whether a nuclear reactor has been designed in accordance with the DID philosophy, a reactor system is considered “safe” if it can tolerate a fixed set of prescribed accident scenarios judged to be important – the so-called DBAs. The early regulators argued that if plants could handle the DBAs, they could also handle any other accidents – an attempt to eliminate the possibility of plant failures from fundamental design flaws and worst possible accidents.

Due to the fact that the deterministic safety analysis relies on DBAs and misses possibly important multiple failure events, more recently the DID concept is supplemented by probabilistic safety information (Fleming and Silady 2002). These best-estimate (rather than conservative) and probabilistic (rather than deterministic) assessments identify potential accident scenarios that could adversely contribute to safety. Specific DID-guided measures can then be taken to reduce safety risks (Delaney et al. 2005). This systematic approach relies on proven engineering, quality assurance, and reliability methods; fundamental safety principles; safety assessment and verification; operating experience; and safety research.

In summary, the concept of DID has evolved into a set of regulatory design and safety principles, which primarily includes:

1. Use of multiple active and/or passive engineered barriers to rule out any single failure leading to the release of radioactive materials.
2. Incorporation of large design margins to overcome any lack of the precise knowledge (epistemic uncertainty) about capacity of barriers and magnitude of challenges imposed by normal or accident conditions.
3. Application of quality assurance in design and manufacture.
4. Operation within predetermined safe design limits.
5. Continuous testing, inspections, and maintenance to preserve original design margins.

The first design and safety principle described above, i.e., multiple barriers, is the essence of DID philosophy, which typically consists of:

- Fuel cladding
- Reactor coolant system
- Containment

In light water reactors, nuclear fuel is generally fabricated in the form of ceramic pellets and put in metal cladding, and hence, the fuel cladding plays a role of the first physical barrier against release of radioactive material from the fuel.

The second physical barrier is the reactor coolant system RCS, which consists of reactor vessel and piping. The components that constitute the RCS pressure boundary are designed, fabricated, constructed, and maintained to protect the public, during any plant transient or natural phenomena such as earthquakes, tornadoes, flooding conditions, winds, ice, etc. Special consideration is given to static and dynamic loads, temperature, and irradiation effects to which the components might be exposed during their lifetime. Included in the design specifications for the components are requirements for safety margins to protect against unexpected internal loadings, undetected internal flaws, changes in material properties, and most importantly uncertainty posed by unknown-unknowns.

The third level of physical DID is the inclusion of physical barriers for the containment or confinement of the source terms (i.e., fission products available for release to the environment)

produced from accidents in the event that the first two levels of defense fail. These multiple barriers protect humans and the environment in a wide range of abnormal conditions by guarding against the possibility of radioactive release.

In addition to the physical barriers, DID principle is also implemented in nuclear power plants in terms of protection systems and engineered safety features (ESF). The protection systems, such as the reactor protection system (RPS), help to keep an off-normal event from escalating into a significant event threatening reactor safety. The design requirements for these protection systems are based on a spectrum of events that could lead to off-normal operations. In the case of the RPS, redundant and independent instrument channels, once activated through processing of signals, automatically initiate a protective action to suppress conditions that could result in exceeding acceptable fuel limits. The operational reliability of the RPS is attributable to its redundancy and thoughtful safety engineering. On the other hand, the ESF are automatically brought into operation in general when their activation thresholds in terms of process parameters are reached as a consequence of failures of other equipment or physical barriers in order to minimize the adverse effect from or suppress the progression of the plant anomaly. These protection systems and ESFs add further margins to the DID concept by postulating, for design purposes, the occurrence of hypothetical accidents that progress beyond what may be considered normal occurrences.

1.4 Design Basis Accidents

DBAs are the set of postulated accidents for which the designer is required to include explicit provisions (defenses in the plant), while remembering that more severe or peculiar accidents can still occur, and ensuring that the plant design has sufficient capability to cope with them. The DBAs are often defined as those conditions that the regulatory bodies require the plant owners/operators to analyze. Clearly, DBAs are postulated accidents and resulting conditions against which the structures, systems, and equipment of a nuclear facility must be assessed. These postulated or anticipated accidents are assumed to cause the most severe consequences within the design boundary (i.e., excluding those events the occurrence of which is highly unlikely), and the estimated consequences are then compared with the permissible dose exposure to an individual at the site boundary. DBAs are discussed in greater details later.

1.5 Single Failure Criterion

A single failure means an occurrence that results in the loss of capability of a component to perform its intended safety functions. Multiple failures resulting from a single occurrence are considered to be a single failure. Fluid and electrical systems are designed against an assumed single failure if neither (1) a single failure of any active component (assuming passive components function properly) nor (2) a single failure of a passive structure, system and, component (SSC) results in a loss of the capability of the system to perform its safety function (assuming active components function properly).

For example, consider a reactor that must receive a given minimum coolant flow rate to prevent its core to experience any damage following certain accident scenario initiators such as a LOCA. The plant cooling systems will be successful if they provide the minimum required flow when needed. This is the injection success criterion for such accident scenarios. The plant

systems can satisfy the single failure criterion (SFC) if the required flow can be provided in spite of the failure of any single component to perform its intended function. This can be achieved through the use of two diverse systems (or one system with two trains), provided that each system (or train or a single system) alone is capable of delivering the required flow on demand.

The two systems (or trains) are said to be redundant if they contain essentially identical components; for example, each train might contain a motor driven pump and several motor operated valves. The trains would be diverse, or partially diverse, if they rely on different energy sources; for example, one train might contain a steam driven pump rather than a motor driven pump.

The notion of SFC was embodied in the US Code of Federal Regulations (CFR) during the early days of the nuclear power industry (USNRC 1977; USNRC 1978; USNRC 2005a). The SFC exists in two major contexts: (1) system design requirements, largely associated with the general design criteria (GDC) of 10 CFR Part 50 Appendix A (USNRC 1999a) which require designing safety-related systems to perform safety functions to mitigate DBA initiating events, assuming a single failure; and (2) guidance on DBA analysis in ► Sect. 15 of Regulatory Guide 1.70 (now updated to Regulatory Guide 1.206 (USNRC 2007)) and of the standard review plan (SRP) (USNRC 2007b). The SFC is required to be applied in safety analysis in order to promote the high reliability of safety functions that are important to safety, and to help ensure that in the event of a single failure the intended safety function can still be performed. Several regulations, guidelines, and programs, including quality assurance requirements, technical specifications, testing-, inspection-, and maintenance-requirements, act in concert with the SFC to promote high system reliability.

However, the SFC has not always led to the design of safety systems whose reliabilities were judged commensurate with the frequency of safety challenges to the plant. The SFC approach also includes other important elements to address phenomena, such as common cause failure whose impacts on plant safety are not mitigated by redundancy in the design of safety functions. Some additional measures to supplement the SFC include the Reactor Oversight Process tracking of safety system availability (USNRC 2006; USNRC 2005b).

1.6 Accident Types

In the safety analysis of nuclear power plants (specifically water-cooled reactors), the potential accidents are typically divided into two types: loss of coolant accidents and transients. Each is further discussed in the following section.

1.6.1 Loss of Coolant Accidents

For many water-cooled reactors, the design basis event that results in the largest potential radiological consequences to the public is a catastrophic break of the largest pipe entering the reactor pressure vessel. Such a break is postulated in spite of the extensive measures taken in the design, construction, testing and inspection, and operation and maintenance of the plant to assure that such breaks will not occur. Given the break, the reactor coolant would discharge freely from both ends of the severed pipe. This type of break is referred to as a “double-ended guillotine break” and usually leads to the most severe calculated consequences.

Because the RCS operates under high pressure, a reactor coolant pipe break would result in rapid discharge of most of the reactor coolant into containment. In PWR containments, cold-water sprays and/or ice racks are provided to condense the steam resulting from this expulsion while in BWRs, the steam would be condensed in the water-filled pressure-suppression pool. Condensing the steam limits containment pressure, which is the driving force for outward leakage. At the end of the “blowdown” (rapid discharge) period, the primary system consists entirely of saturated steam at the same pressure as that of the containment. In fact, a large-break LOCA or main steam-line break usually determines the peak internal pressure that the containment should be designed to accommodate.

In a large-break LOCA, the reactor would immediately go subcritical due to the substantial and rapid loss of reactor coolant and the subsequent reduction in neutron moderation. Successful actuation of the (RPS), which generates a trip signal, would make the reactor subcritical when reflooded with emergency coolant. However, there would still be considerable thermal energy generated in the fuel from the decay of radioactive fission products. Immediately after shutdown, the generation rate of this “decay heat” is about 7% of the thermal power during normal operation. For example, a 1,000 MWe nuclear plant generates about 3,100 MWt during full power operation, but still generates about 225 MWt immediately after shutdown. The decay heat generation rate decreases rapidly, but will take a few days until it reaches a reasonably low level. However, if emergency cooling water were not supplied to remove heat from the core following the pipe break, core temperature would increase to the point where energetic chemical reactions would occur between hot cladding and residual water-steam in the reactor pressure vessel. Given a prolonged failure to cool the core, large quantities of hydrogen could be generated, portions of the core would melt, and fission products would be released to the containment and possibly to the environment.

In order to limit the consequences of a LOCA, each LWR is provided with an ECCS. An automatic control system senses the occurrence of a LOCA and actuates and coordinates the operation of the different parts of the ECCS as they are needed. The function of the ECCS is to supply water to the core (via spray and/or flooding systems) to cool and limit the temperature increase of the cladding, thus preventing significant core damage and release of radionuclides from the fuel rods.

The US regulations (and similar requirements exist in IAEA guidelines), according to 10 CFR 50.46 and Appendix K of 10 CFR 50 (USNRC 2003a; USNRC 1999a), require that the ECCS of light water reactors satisfy the following acceptance criteria:

- Peak cladding temperature up to 2,200 °F (1,204 °C).
- Oxidation level up to 17% of the cladding thickness.
- Hydrogen generation from hot cladding-steam less than 1% of the total available.
- The core geometry must remain coolable.
- Long-term cooling must be provided.

In a deterministic safety analysis, approved codes and methods are used to show that the safety systems meet the above requirements under conservative assumptions during the analysis.

1.6.2 Transient Events

Transient events are referred to those events that result in a reactor trip but keep the reactor-coolant boundary intact, as opposed to the LOCAs. Transients could occur from a variety of

causes, such as equipment failure or human error. The three principal areas of interest for transients are instances where the reactor power increases, the coolant flow decreases, or the coolant pressure increases. Each of these three instances could lead to a core melt or a breach of the RCS.

Transients are of two broad categories – anticipated transients, such as loss of off-site power or loss of feedwater transients, and unanticipated transients such as turbine missiles or station blackout. The assessment of the frequencies and consequences of these transients typically indicate that the potential contribution of the unanticipated transients to the overall risk is small compared to the anticipated transients. The majority of the analyses show that the most important transients in terms of their risk impact involved the loss of offsite power and the loss of plant heat removal systems.

1.7 General Design Criteria

In the US nuclear plant safety analyses, until 1965 there were no written criteria against which the various designs could be compared, and there was essentially no review of the detailed design approach, which actually determines the levels of safety achieved. As the number of new plant applications increased, there was a strong desire to restructure the licensing review process. In the spring of 1965, in response to anticipated recommendations of an outside review panel, the AEC staff began drafting what would later become the GDC, discussed in Appendix A of 10 CFR 50 (USNRC 1999a).

The GDC established minimum requirements for the principal design criteria, which an application for a construction permit must include for the proposed facility. The principal design criteria establish the necessary design, fabrication, construction, testing, and performance requirements for structures, systems, and components important to safety so as to provide reasonable assurance that the facility can be operated without undue risk to the health and safety of the public. The GDC codified in the US regulation do not provide specific or quantitative bases for establishing the safety adequacy of the proposed facility. The detailed design and its acceptability were deliberately left to the “engineering judgment” of the designer and the regulator, respectively.

The GDC addresses 64 broad issues in six major categories:

1. Overall requirements
2. Protection by multiple fission product barriers
3. Protection and reactivity control systems
4. Fluid systems
5. Reactor containment
6. Fuel and reactivity control

Several core criteria included in the first category earlier, i.e., “overall requirements,” are discussed in the following section, since these are particularly important and impact many aspects of reactor safety.

1.7.1 Quality Control Criterion

Structures, systems, and components important to safety must be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions they

perform. A quality assurance program must be established and implemented in order to provide adequate assurance that these SSCs will satisfactorily perform their safety functions. Appropriate records of design, fabrication, erection, and testing of SSCs important to safety must be maintained by or under the control of the nuclear power unit licensee throughout the life of the plant.

1.7.2 Design Bases for Protection against Natural Phenomena

Structures, systems, and components important to safety must be designed to withstand the effects of natural phenomena such as earthquakes, tornadoes, hurricanes, floods, tsunami, and seiches without loss of capability to perform their safety functions. The design bases for these SSCs are required to reflect:

1. Appropriate consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated.
2. Appropriate combinations of the effects of normal and accident conditions with the effects of the natural phenomena.
3. The importance of the safety functions to be performed.

1.7.3 Fire Protection

Structures, systems, and components important to safety must be designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions.

In 1980, the US NRC formally proposed Appendix R to 10CFR50 to state the minimum acceptable level of fire protection for power plants. Appendix R contains four general requirements to (1) establish a fire protection program, (2) perform a fire hazard analysis, (3) to incorporate fire prevention features, and (4) to provide alternative or dedicated shutdown capability.

1.7.4 Environmental and Dynamic Effects Design Bases

Reactor accidents may lead to harsh environmental conditions that may challenge the operation of components and systems or threaten the integrity of structures. Examples of environmental conditions that can occur include high-temperature steam, high pressure, radiation, missiles, and pipe whip.

For safety systems to function during an accident, they must be designed to withstand the expected environments. Therefore, this criterion states: "Structures, systems, and components important to safety must be designed to accommodate the effects of and to be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including loss-of-coolant accidents."

1.7.5 Sharing of SSCs

This criterion is intended to address features of a multiunit site that could allow problems to propagate from one unit to another. The criterion states: “Structures, systems, and components important to safety shall not be shared among nuclear power units unless it can be shown that such sharing will not significantly impair their ability to perform their safety functions, including, in the event of an accident at one unit, an orderly shutdown and cooldown of the remaining units.”

Similar to the US requirements, there are several main technical principles that are essential to the successful realization of safety technology for nuclear power plants. These principles used by IAEA are briefly discussed in ► [Sects. 1.7.6–1.7.14](#).

1.7.6 Proven Engineering Practices

Nuclear power technology should utilize engineering practices that are proven by testing and experience, and which are reflected in approved codes and standards. The design and construction of advanced power plants should rely as much as possible on experience from older operating plants or on the results of research programs, large integral facilities and prototypes. Standardization can offer economic payoff and indirect safety advantages by focusing on the resources of designers, regulators, and manufacturers on specific design and fabrication methods.

1.7.7 Quality Assurance

Quality assurance is applied to ensure with high confidence that all SCCs, services, and tasks performed meet specified requirements. High quality in equipment and human performance (HP) is most central to nuclear plant safety. The goal is to ensure that the equipment functions and individuals perform in a satisfactory way. These practices apply to the entire range of activities in design, construction, installation, and to the control of procedures in plant testing, commissioning, operation, and maintenance.

1.7.8 Self-Assessment

Self-assessment for critical activities at a nuclear plant ensures the involvement of plant staff performing line functions in detecting problems concerning safety and performance and solving them.

1.7.9 Peer Reviews

Independent peer reviews make practices and programs employed at plants performing well accessible and allow their implementation to improve safety. International organizations typically performing operational peer reviews are the World Association of Nuclear Operators (WANO) and the IAEA through their Operational Safety Review Teams.

1.7.10 Human Factors

Plant staff occupied in safety-related activities are trained and qualified to perform their respective duties. Reduction of human error in nuclear power plants may be achieved by assisting operators in making correct decisions and minimizing incorrect decisions, and by providing means for detecting and correcting or compensating for error. "Human factor improvements" are necessary in plant hardware (e.g., in ergonomic layout), plant procedures, training, and other areas to help prevent or mitigate human error. To keep the plant within the boundaries of a domain of safe operation, approved procedures for operation should be followed. To ensure this, staff training and retraining receive strong emphasis, with classroom, simulator, and plant-based studies.

1.7.11 Safety Assessment and Verification

As noted earlier two methods of analysis are possible: deterministic and probabilistic. In the deterministic method, design basis events are chosen to encompass a range of related possible initiating events that could challenge the safety of the plant. Analysis is used to show that the response of the plant and its safety systems to design basis events satisfies predetermined specifications for both the performance of the plant itself and meeting safety criteria.

Probabilistic analysis is used to evaluate the likelihood of any particular sequence and its consequences. This evaluation may take into account the effects of mitigation measures inside and outside the plant. Probabilistic analysis is used to estimate risk and especially to identify the importance of any possible weak link in design. The probabilistic method can be used to aid in the selection of events requiring deterministic analysis and the other way around.

1.7.12 Radiation Protection

A system of radiation protection practices is followed in the design, commissioning, operational, and decommissioning phases of nuclear power plants. Measures are then taken to protect workers and the public against the harmful effects of radiation in normal operation, anticipated operational occurrences and accidents.

1.7.13 Operating Experience and Safety Research

Operating experience and the results of safety-related research are exchanged, reviewed, and analyzed. The nuclear power plant owner/operator maintains an effective system for collecting and interpreting operating experiences, and sharing safety significant information rapidly among the plant staff. The root causes of accidents are reanalyzed, and events regarded as precursors of severe accidents are identified and actions are taken to prevent any recurrence.

1.7.14 Defense against Severe Accidents

Some highly unlikely plant accidents that are Beyond Design Basis Accidents (BDBA) may arise due to multiple failures of safety systems leading to significant core degradation that may jeopardize the integrity of many or all of the barriers to the release of radioactive material. These event sequences are called severe accidents.

Consideration is given to these severe accident sequences, using a combination of engineering judgment and deterministic analyses. Acceptable measures need not necessarily involve conservative engineering practices used in evaluating DBAs, but rather should be primarily based upon realistic or best estimate assumptions, methods, and analytical criteria. On the basis of operational experience, relevant safety analysis, and results from safety research, design activities for addressing severe accidents shall take into account important accident scenario events that may lead to a severe accident through a combination of probabilistic methods, deterministic methods, and sound engineering judgment.

1.8 Requirements and Standards for Nuclear Safety

1.8.1 American National Standard Nuclear Safety Criteria

In late 1965, around the time when the AEC was ready to publish the first version of their GDC, the industry prepared supplementary criteria to complement and implement the GDC. Objectives included: simplifying and streamlining the licensing procedures, providing a means to obtain industry-wide agreement on objectives, providing a means to uniformly judge the protection afforded the public, and avoiding the necessity of government articulation of such requirements in the form of rulemaking.

A series of drafts was produced and the final version, known as ANSI N18.2–1973 (ANS 1973), was eventually approved. This ANSI Standard was developed to amplify the guidance provided by the GDC. The criteria contained therein were aimed at providing a degree of assurance that PWR facilities would be designed, constructed, and can be operated without undue risk to the health and safety of the public. However, the focus of these criteria was placed on design requirements. Operating, maintenance, and testing requirements other than those affecting design, although of great safety significance, were not included.

It is notable that the ANSI N18.2–1973 Standard duly cautioned that: (1) simple adherence to the criteria might not suffice for satisfying the requirement of assuring public health and safety; and (2) an owner or designer of the facility has a responsibility, even at the design state that goes beyond the degree of safety afforded by the criteria. As such, in addition to considering these criteria and other guidance such as the GDC, the following requirements were made.

1. Identify all safety design criteria for the proposed facility and ensure that they incorporate all features for structures, systems, and components required to protect public health and safety
2. Ensure by analysis, experiment, comparison to accepted design, or experience that the fulfillment of all these safety design criteria can and will be realized.

As opposed to the GDC, the ANSI N18.2–1973 Criteria were presented in a format to provide maximum usefulness in system design, encompassing:

- Categorization of plant conditions to be considered in design
- Safety classifications of reactor containment and components
- Barrier integrity criteria
- Plant safety analysis
- Specific system design criteria

The full spectra of plant conditions were identified in accordance with their anticipated frequency of occurrence as follows:

1. Condition I: Normal Operation
2. Condition II: Incidents of Moderate Frequency
3. Condition III: Infrequent Incidents
4. Condition IV: Limiting Faults

Condition I occurrences are operations that are expected frequently or regularly in the course of power operation, refueling, maintenance, or maneuvering of the plant. Condition II occurrences include incidents that may occur during a calendar year for a particular plant. Condition III occurrences include incidents, any one of which may occur during the lifetime of a particular plant. Condition IV occurrences are faults that are not expected to occur, but are postulated because their consequences would include the potential for the release of significant amounts of radioactive material. Condition IV faults are the most drastic to be designed against, and thus represent the limiting design case. Note that large fleets of operating plants were licensed according to this categorization of plant conditions defined in ANSI N18.2–1973, although it was later replaced by ANSI/ANS-51.1–1983 (ANS 1983).

The basic principle applied in the ANSI N18.2–1973 Standard was that the plant should be designed such that the most frequent occurrences yield little or no adverse consequence to the public and such that the improbable extreme situations, having the potential for the greatest adverse consequence to the public, shall have a low probability of occurrence. Protection system and engineered safety feature functioning was required, where applicable, in fulfilling this principle.

In order to facilitate the design process, the following design requirements were specified for each plant condition in the ANSI N18.2–1973 Standard:

1. Design Requirement for Condition I: Condition I occurrences shall be accommodated with margin between any plant parameter and the value of the parameter which would require either automatic or manual protective action.
2. Design Requirement for Condition II: Condition II occurrences shall be accommodated with, at most, a shutdown of the reactor with the plant capable of returning to operation after corrective action. Any release of radioactive materials in effluents to unrestricted areas shall be in conformance with 10 CFR Part 20, “Standards for Protection Against Radiation.” By itself, a Condition II incident shall not lead to a more serious incident of the Condition III or IV type, without other incidents occurring independently. A single Condition II incident shall not cause consequential loss of function of any barrier to the escape of radioactive products.
3. Design Requirement for Condition III: Condition III incidents shall not cause more than a small fraction of the fuel elements in the reactor to be damaged. The release of

radioactive material due to Condition III incidents may exceed guidelines of 10 CFR 20, but shall not be sufficient to interrupt or restrict public use of those areas beyond the exclusion radius. A Condition III incident shall not, by itself, generate a Condition IV fault or result in a consequential loss of function of the RCS or reactor containment barriers.

4. Design Requirement for Condition IV: Condition IV faults shall not cause a release of radioactive material that results in an undue risk to public health and safety exceeding the guidelines of 10 CFR 100, "Reactor Site Criteria." A single Condition IV fault shall not cause consequential loss of required functions of systems needed to cope with the fault including those of the RCS and the reactor containment system.

1.9 US Regulatory Requirements for Deterministic Safety Analyses

The Code of Federal Regulations (CFR) of the US is a codification of the general and permanent rules published in the Federal Register by the Executive departments and agencies of the Federal Government. The Code is divided into 50 titles which represent broad areas subject to federal regulation. Nuclear regulations are contained in Title 10 – Energy (USNRC 1956).

Of the many parts in 10 CFR, the following four parts are especially relevant to safety analysis of nuclear power plants.

1. 10 CFR 20 – Standards for protection against radiation
2. 10 CFR 50 – Domestic licensing of production and utilization facilities
3. 10 CFR 52 – Licenses, certifications, and approvals for nuclear power plants
4. 10 CFR 100 – Reactor site criteria

Title 10, Code of Federal Regulations, Part 50, i.e., 10 CFR 50, has been used as a major compilation of regulations with respect to design, construction, and operation of commercial nuclear power plants. 10 CFR Part 52 was recently published for the issuance of combined licenses (COLs) for nuclear power plants. In order to guide COL applications, Regulatory Guide 1.206 (USNRC 2007a) was published in 2007 and information in this regulatory guide is reflected in NUREG-0800 (USNRC 2007b), "Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants." This standard review plan (SRP) is used by the US NRC in reviewing applications for early site permits, standard design certifications, COLs, and other activities addressed by 10 CFR Part 52.

Of these regulations, the key principle of nuclear reactor regulation in the USA with regard to prospective safety analysis is reflected in the following statement that is included in 10 CFR 50.34, Contents of Applications; Technical Information: "It is expected that reactors will reflect through their design, construction and operation an extremely low probability for accidents that could result in the release of significant quantities of radioactive fission products." For the sake of demonstration of such expectations, the applicants for a construction permit, a design certification, or combined license are required to perform a safety assessment of the site and a safety assessment of the facility.

These safety assessments must determine that:

1. An individual located at any point on the boundary of the exclusion area for any 2 h period following the onset of the postulated fission product release, would not receive a radiation dose in excess of 25 rem total effective dose equivalent (TEDE).

2. An individual located at any point on the outer boundary of the low population zone, who is exposed to the radioactive cloud resulting from the postulated fission product release (during the entire period of its passage), would not receive a radiation dose in excess of 25 rem TEDE.

The whole body dose of 25 rem has been stated in the US regulation to correspond numerically to the once in a lifetime accidental or emergency dose for radiation workers which, according to NCRP recommendations at the time, could be disregarded in the determination of their radiation exposure status. However, its use is not intended to imply that this number constitutes an acceptable limit for an emergency dose to the public under accident conditions. Rather, this dose value has been set forth as a reference value, which can be used in the evaluation of plant design features with respect to postulated reactor accidents, in order to assure that such designs provide assurance of low risk of public exposure to radiation, in the event of such accidents.

➤ **Sect. 15**, “Accident Analyses,” contained in Revision 3 of Regulatory Guide 1.70, “Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants – LWR Edition,” and had been used by the US NRC as a primary guidance of how applicants of a nuclear power plant should evaluate the safety of the plant (USNRC 1978). This regulatory guide issued in 1978 has been updated in 2007 into Regulatory Guide 1.206 (USNRC 2007a) to reflect current information requirements for COL applications.

As opposed to the four categories of plant conditions discussed in the ANSI/ANS N18.2–1973 Standard, each initiating event for safety analysis is classified in ➤ **Sect. 15** of NUREG-0800 (USNRC 2007b), so called the SRP, as either an anticipated operating occurrence (AOO) or a postulated accident. In both Appendix A to 10 CFR 50 and ➤ **Sect. 15** of the SRP, AOOs are defined as those conditions of normal operation that are expected to occur one or more times during the life of the nuclear power unit and include but are not limited to loss of power to all recirculation pumps, tripping of the turbine generator set, isolation of the main condenser, and loss of all offsite power. The SRP indicates that AOOs are also known as Condition II and III events. On the other hand, the SRP defines postulated accidents as unanticipated conditions of operation (i.e., not expected to occur during the life of the nuclear power unit). It also indicates that postulated accidents are alternatively known as Condition IV events. In ➤ **Sect. 15** of the SRP, various requirements for safety analysis are specified as to how to identify the limiting events that will be analyzed in detail, how to determine the specific accident sequences (e.g., consideration of single failure and coincident occurrence of a loss of offsite power), what acceptance criteria to apply for specific events or event sequences, and so on.

1.10 Safety Features for Future Nuclear Plants

Future plants continue to improve the DID safety features. Prevention of accidents remains the highest priority, but controlling the course of accidents and mitigating their consequences, if they happen, are also very important.

An important advantage of future plants is their ability to incorporate corrections to deficiencies identified in the past. The use of a deterministic checklist for such problem areas and their proposed resolution will ensure that no significant past difficulty is overlooked. Future plants have another advantage, because they can implement the results of research and

development programs, including those relating to new materials, improved coolant chemistry, methods of making best estimate predictions of operating margins and their uncertainties, and the findings from a large number of other safety analyses and research work. But it is important that features incorporated into future plants be fully proven through adequate tests and, preferably, demonstration in operating plants.

Reducing the frequency of equipment failures and the number of human errors enhances accident prevention. For equipment failure, the reduction in the likelihood of occurrences is achieved by simplifying the design and reducing the number of active components, such as pumps, which can fail to operate when demanded. Another approach is to increase the tolerance to equipment failure, thereby reducing the potential adverse impact of transients on the plant. Further capability of accident prevention may be achieved by improving human-machine interfaces or taking advantage of proven information and digital technology. When computer systems are utilized for safety functions, sufficient precautions must be taken against potential common-cause failures of their constituents comprising hardware, firmware, and software. The quality and reliability of these systems and additional measures such as an appropriate degree of diversity must be considered. In addition, the production process must include integral testing of software and hardware systems and good practices for software verification and validation.

Another opportunity to improve accident prevention is to assess the measures taken at different levels of defense in depth and, where practical, to eliminate dependence between systems. Finally, adequate provisions in terms of space and installation are necessary to improve the performance and quality of nondestructive inspections and maintenance work. Plant designers and owners/operators may provide additional margins in as many areas as appropriate for investment protection, operational flexibility, and increased safety assurance.

Accident mitigation capability should be enhanced to the extent practically achievable to reduce the consequences of radioactive releases. For future nuclear power plants, the design features related to the prevention and mitigation of accidents, including severe accidents, will be determined not only on the basis of deterministic analysis, but also best estimate probabilistic considerations as well as the application of numerical safety targets and engineering judgment. Notably, the practical elimination of accident sequences, which could lead to large, early radioactive releases, is based, as far as necessary, on detailed deterministic and/or probabilistic studies.

The role of deterministic safety analysis would be paramount, but probabilistic safety assessments (PSAs) play a critical role at the design stage as a useful tool for in-depth analysis of the contributions of the different accident sequences to the risk. This is the topic of the remaining sections of this chapter. Reaching a final decision about features to be incorporated in future nuclear power plants is an iterative process, with initial judgments made by the designers based on experience and research results and with the help of PSAs. This is followed by a review by plant owners/operators and regulators to confirm that an appropriate decision has been made. This process of careful evaluation and decision making leads to a consistent and robust set of design features.

The risks associated with future nuclear power plants will become very low, due to the reduction in both the frequency of occurrence of potential accident scenarios and the radiological consequences resulting from the accidents. However, this statement supposes that careful attention will be paid to the possibilities of common-mode failures and the uncertainties still prevalent in the understanding of severe accident phenomena. For these reasons, engineering judgment will be important in evaluating new design features.

2 Evolution of Probabilistic Safety Assessment and Applications

As was stated in ► Sect. 1, the primary means for assuring safety in nuclear power plants has been deterministic methods. This concept while being strong has shown to be insufficient by itself in ensuring nuclear safety, and as a result, probabilistic methods would be needed to fill such shortcomings.

A comprehensive evaluation of reactor safety was performed in early 1970s using probabilistic methodologies to the feasible extent in an AEC study called the reactor safety study (RSS) or WASH-1400. This RSS was the major milestone in the history of probabilistic safety analysis because it not only established the basic methodology but also spurred a large number of similar studies throughout the international nuclear power community. After a brief introduction to safety issues in nuclear and aerospace industries, this section discusses the RSS as well as the historical perspectives of probabilistic safety analysis following the RSS. Also included herein is a description of various PSA applications that are conducted to enhance safety of nuclear power plants and improve efficiency in the plant operation and the regulatory activities.

2.1 Safety Issues in Nuclear and Aerospace Industries

2.1.1 Safety Issues in Nuclear Industry

While formal consideration of risk and reliability was not a concern of the Atomic Energy Commission (AEC), it acknowledged, however, that it could not eliminate all risks through its DID principle and design-basis accident methods. The Advisory Committee on Reactor Safeguards (ACRS) of the AEC informed the Congress in 1956 that because of technical uncertainties and limited operating experience, “the determination that the hazard is acceptably low is a matter of competent judgment.”

In 1957, WASH-740 (USAEC 1957), the first comprehensive look at the consequences of a large nuclear accident, was published by the AEC. The purpose was to help focus Congressional deliberation of the Price–Anderson Act on the potential harms from reactor accidents. The Price–Anderson Act was being considered to provide supplemental government insurance for private nuclear reactors. WASH-740 originally looked only at the 200 MW class of reactors then in operation and predicted potential damage due to an accident in the \$7 billion range. WASH-740 estimated the risk for a serious reactor accident as 1×10^{-6} per reactor-year of operation, a value still within the range of probabilities being estimated today for an occurrence of a large early release of radiation due to reactor accidents. But the Price–Anderson Act arbitrarily used a \$500-million of insurance figure, above the commercial insurance of \$60-million provided by private insurance companies. After it was revised in 1964–1965, when larger reactors were designed, the worst-case nuclear accident cost rose to \$17-billion (Wood 1983). The WASH-740 study focused on the dangers of large LOCAs as the leading source of worst radiation release into the environment.

As the reactor safety systems continued to grow in size and complexity, a new method of analysis was needed to produce reasonably more accurate risk estimates. At the urging of the ACRS, which first troubled about the so-called China syndrome, the AEC established a special task force to investigate the core-melt problem in 1966. The task force report that was published

in 1967 offered assurances about the improbability of a core meltdown and the reliability of emergency core cooling designs, but it also acknowledged that a LOCA could cause a breach of containment if the ECCS failed to operate. From this point on, the containment could no longer be regarded as an unbreakable final barrier of radioactivity. This represented a key milestone as it modified the fundamental approach to reactor safety. Once the AEC realized that under some circumstances the containment building could fail, the key to protecting the health and safety of the public shifted to preventing accidents severe enough to threaten containment.

In the late 1960s, two papers that brought PSA to the forefront of nuclear engineering thought was published. The first was a 1967 paper presented at IAEA's Vienna conference by F.R. Farmer entitled "Reactor Safety and Siting: A Proposed Risk Criterion" (Farmer 1967). This paper included the now famous Farmer Curves and concentrated on the effects of iodine-131. Another paper was a 1969 Science article "Social Benefit versus Technological Risk" by Chauncey Starr, which further elaborated on risk perception, and many of Farmer's points (Starr 1969). In the meantime, in 1966, the AEC asked General Electric, the contractor at Hanford, and Du Pont, the contractor at Savannah River, to perform calculations on the safety of the plutonium production plants that they operated. Partly influenced by Farmer's paper, General Electric showed, using a very simplistic probabilistic model, that the N-Reactor had a one-in-a-million chance per year for a catastrophic failure because each of the three major subsystems would only fail once-in-one-hundred per year (Carlisle 1997). General Electric and Douglas United Nuclear, the subcontractor that assumed operational control of the N-Reactor in 1967 then claimed that such a low probability meant that for all practical purposes, the chance of a catastrophic failure was zero, a conclusion that the AEC and others disputed (USAEC 1966).

To address the issues of safety, AEC concluded that the complexities associated with the design and operation of the reactors operating at that time exhibited so many technical challenges that a quantified risk assessment would be impossible to produce. One reason for this was that the probabilistic methodologies lacked sophistication and rigor, and the information required was not fully available (Ford 1977).

By 1971, nuclear critics were expressing resentment to the AEC because of the licensing of several reactors under review and its conflicting mission of both regulating and promoting nuclear power. However, in 1974, the AEC's regulatory programs came under such strong attacks that the Congress decided to abolish the agency. Supporters and critics of nuclear power agreed that the promotional and regulatory duties of the AEC are in conflict and should be assigned to separate agencies. The Energy Reorganization Act of 1974 created the Nuclear Regulatory Commission (NRC), which assumed the responsibility for civilian nuclear power regulation and assuring the protection of the health and safety of the public.

2.1.2 Safety Issues in Aerospace Industry

Another industry in which issues of safety and risk were of paramount importance was the aerospace industry. The Boeing Company, in conjunction with Bell Laboratories, pioneered the use of fault tree analysis during the design of the Minuteman missile for the Air Force during the 1960s to prevent inadvertent launches. In 1966, Pan Am Airlines placed an order with the Boeing Company to build the Boeing-747. Because the Boeing-747 would be the largest commercial jet in operation, boeing engineers felt that it would be important to look at the

safety systems of the plane in a different manner than they had in previous aircraft designs. The method they chose was fault tree analysis, which provided a deductive, systematic, and holistic assessment of the airplane and highlighted among the faults modeled, the critical ones and effects of such faults on the plane. This allowed the designers to appreciate how and why the failure of one system or component would affect other systems (Ericson 1999).

National Aeronautics and Space Administration (NASA) began to use probabilistic risk assessment methods in 1967, following the disastrous fire on Apollo 1. Engineers from the Boeing Company helped complete a fault tree analysis for the entire Apollo system. They relied on highly conservative measures and data and estimated failure probabilities for Apollo missions to range 0.1–0.8 per mission; a range that was higher than the actual experience, and subsequently led to a distrust of probabilistic risk assessment results. However, following the Challenger explosion in 1986, probabilistic risk assessment at NASA was revived, and the Columbia break-up in 2003 reiterated the need for such analyses. NASA used risk assessment and a combination of fault and event trees methods borrowed from the nuclear industry to model possible accident scenarios for the shuttle and International Space Station (ISS) programs. One risk study performed by the US Air Force in 1983 calculated the chances of a space shuttle solid rocket booster failing during operation to be about 1 in 35, a number disputed by NASA management (Colglazier and Weatherwas 1986).

Risk assessment methods in the nuclear industry benefitted from the experience of the aerospace industry in the early 1970s. However, in the late 1980s when the need for systematic safety assessment became apparent in the space industry, it was the aerospace industry that turned to and relied primarily on the experience of the nuclear industry.

2.2 Reactor Safety Study (WASH-1400)

2.2.1 Motivation – ECCS Issue and Loss of Fluid Tests

Often bitter debates over the reliability of ECCSs, reactor pressure vessel integrity, and the likelihood of large accidents consumed the AEC, the Congress, the nuclear industry, environmentalists, and the media. In the late 1940s and most of the 1950s, public attitudes toward the technology were highly favorable as the opinion polls on the subject revealed. In the late 1950s and early 1960s, however, the public became more aware and worried about the hazards of radiation, largely as more was learned about radioactive fallout from nuclear weapons testing. Throughout the 1960s, there was a desire and interest among the public to know whether or not nuclear plants were safe. This desire for safety assurance became more urgent in the late 1960s and early 1970s, as the organized opposition to nuclear power grew and characterized AEC's safety criteria used for licensing nuclear plants as inadequate and inconsistent with respect to the apparent safety significance of various systems, structures, and components of the plants.

Of the many issues that arose these years, the most critical issue that led to an integrated assessment of safety, i.e., the RSS, was the concern about a LOCA that might lead to a core melt if the ECCS fails. A special task force established by the AEC to look into the problem of core melting indicated that the containment could no longer be regarded as an inviolable barrier to the escape of radioactivity since a LOCA could cause a breach of the containment if the ECCS failed to perform.

Therefore, the AEC performed a series of experiments at the Reactor Test Facility in Idaho using a small-scale reactor mockup. The loss of fluid tests (LOFT) suggested that the ECCS might not work as well as planned as steam build-up could prevent injection of water into the core and lead to core damage (Kouts 1998). As a result of Congressional requests coupled with concerns over the LOFT results, the AEC asked Professor Norman Rasmussen of MIT for his help to initiate and run a study of the assessment of safety of the nuclear plants in the United States.

2.2.2 RSS Staff

The staff of the RSS, or oftentimes called WASH-1400 (USNRC 1975), consisted of about 40 scientists and engineers, drawn from industry, academia, and government service. In addition to Saul Levine, seven full-time participants were the employees of AEC. Many were experts in particular reactor safety systems and some were experts in risk assessment. Also, several outside experts worked in consequence analysis – modeling the release and health effects of radiation in the environment, in which Rasmussen showed a keen interest.

2.2.3 Fault Trees and Event Trees

The RSS initially used fault trees as the basis for reactor risk calculations. The prototype fault trees for both the BWR (Peach Bottom Atomic Power Station, Unit 2) and PWR (Surry Power Station, Unit 1) designs were developed. Although fault trees were developed for almost all of the major safety-related systems, the team realized that integrating the overall fault tree analysis for the entire nuclear power plant was too complex of an undertaking for the RSS, given constraints in time and resources.

This led to the development of the event tree concept to model the approximate timeline of the possible accident scenarios. Originally borrowed from the decision analysis, the study proposed the event tree method. Event tree methodology remedied the constraints in time and resources associated with relying on fault tree analysis alone. Later the event tree approach became a predominant force in PSAs.

The event trees looked at two separate areas. The first covered failures in major systems, such as the engineered safety systems. The second investigated the ability of a nuclear power plant's containment system to prevent the spread of radiation in the case of an accident. Event trees start with an initiating event that causes the plant to enter a transient from its steady state operating condition.

2.2.4 Initiating Events

Initiating events, usually a breach in the coolant system integrity or a reactor transient, covered several possibilities that the AEC did not consider at that time. These potential problems included the possibility of reactor vessel failure and steam generator failures which had been treated by the AEC as events with negligibly small likelihoods due to the stringent quality requirements for the components. The use of event trees was a pivotal decision that made PSA a practical reality.

In connection with the aforementioned concerns over the ECCS performance, it may be noted here that these concerns from the LOFT experiments did not translate into full-scale power reactor safety systems due to scaling issues. Six specific LOCAs were analyzed in detail as initiating events that might occur in a PWR by the RSS:

- Large pipe breaks (larger than 6 in. diameter)
- Intermediate pipe breaks (2–6 in. diameter)
- Small pipe breaks (less than 2 in diameter)
- Large disruptive reactor vessel ruptures
- Gross steam generator ruptures
- Ruptures in systems that interface with the RCS

After a LOCA occurs, the ESF of a power plant are used to reduce or minimize the amount of radioactive material that reaches the environment. One key system of the ESF is the ECCS. Examples of ESFs include an airtight containment building and large tanks of water and pumps to ensure water flows into the reactor vessel in case of a leak. The goal of the event tree was to decompose any possible process, which could occur following an initiating event that results in the release of radiation, into a set of discrete failure events such that the probabilities of such events can be estimated. Fault trees were used to model the probability of the events included in the event tree. Therefore, each event tree traced the initiating event all the way through to the eventual failure of containment, and determined the probability of the containment failure.

Besides LOCAs, the RSS team investigated several types of reactor transients as possible initiating events for reactor system failure. In the study, a transient was defined as any significant deviation from the normal operating value of any of the key reactor operating parameters – including all non-LOCA situations that could lead to fuel heat imbalances.

2.2.5 Failure Data

By narrowing down the possible initiating events that could cause a radiation release, the event trees allowed the RSS team to reduce the particular fault trees that needed to be investigated. One problem with the method proved to be lack of data to estimate the probability of failure for many of the components involved – a fact noted both in the RSS itself, and in the various criticisms of it. The RSS used generic data derived primarily from similar basic components (pumps, valves, etc.) used by related industries or the military. Additional analyses into both common-cause failures addressing interdependencies within the systems, and human errors addressing external factors had to be performed.

Using fault trees, very complex systems could be broken down into constituent parts and failure probabilities could be assigned to each segment. The failure probabilities took into account the human and common-cause failures mentioned above. For the RSS, fault trees were developed for essentially all of the major individual systems included in the event trees.

2.2.6 Uncertainty Analysis

The accuracy of the study was undoubtedly the best when real-world data based on the same type of equipment used in the reactors was available. Often, other industrial data had to be used – with component failure rates and uncertainties increased, in some places substantially,

due to the unique operating environment of a nuclear reactor, especially during an accident, where exposure to high-temperature steam and radiation could cause component failure. In addition judgment from the experts in the field was used. To account for uncertainties due to limited data, failure probabilities of the events modeled were represented by lognormal distributions instead of point estimates. Because the typical probability of failure for the complete system was so small, even a factor of 100 alteration in the failure probability of most components would not produce much overall change in the system failure probabilities or consequently in the reactor safety calculations. Some system components carried more weights through the process and their associated uncertainties would produce a greater uncertainty for the entire system, but typically these systems had a much smaller uncertainty associated with their failure probabilities.

Most of the failure rates and probabilities used in the study had uncertainties on the order of a factor of 10–100; in some cases – for very low failure rates – the error factor was as much as 1,000. The study used a Monte Carlo method to calculate the overall uncertainty associated with estimated risks, assigning a lognormal distribution to the probability of failure of components and events.

2.2.7 Sensitivity Analysis

Within both the fault trees and event trees, there was no guarantee that all of the various modes leading to significant reactor failure were captured in the study, but it must be noted that the team had significant modeling experience as well as reactor operation and safety experience. All the systems associated with the primary and secondary core cooling loops and the safety systems were analyzed. The level of detail used in the fault tree could also be questioned, but the study used sensitivity tests to determine whether the fault trees had gone into more details than was needed, and determined that the level of detail was adequate.

2.2.8 Consequence Analysis

Following the attempts to model what would happen in the reactor during an accident, required the corresponding calculations of potential radiation releases from the reactor into the containment and ultimately into the environment. After the amount of radiation release was known, the consequences (expected human, economic, and environmental losses) could be estimated. The consequence section of the study was in some ways the most surprising. Before the RSS was released, the general feeling in the nuclear industry was that the consequences of a severe reactor accident would automatically be massive, but the RSS showed that most accidents that led to radiation release would only have small consequences.

The most important element of the consequence analysis was estimation of human exposures and subsequent fatalities and health effects due to any radiation released to the environment. Using the known meteorological and demographic data for each of the existing or planned 68 sites for nuclear reactors in 1974, the RSS was able to calculate the expected radiation pathways and the effects on the nearby residents. The goal was to estimate the most “realistic” radiation effects, by relying on best estimate values and avoiding, as much

as possible, any use of conservative assumptions. Doses from five potential exposure modes were used.

1. The external dose from the passing cloud (plume).
2. The dose from internally deposited radionuclides which are inhaled from the passing cloud.
3. The external dose from the radioactive material which is deposited on the ground.
4. The dose from internally deposited radionuclides which are inhaled after resuspension.
5. The dose from internally deposited radionuclides that are ingested after ground contamination.

Three kinds of effects of radiation were calculated from the total human population dose – early fatalities (within 1 year of exposure), early illnesses (people needing medical treatment), and long-term health effects (additional cancers occurring after a few years). The RSS investigated more than a thousand core-melt scenarios for the PWRs, which were sorted into 38 categories of sequences.

2.2.9 Release Categories

After running a computer code, specially developed to calculate the amount of various radioisotopes released (the CORRAL code) for each of the 38 sequences, the results were sorted into one of nine broad release categories. Similarly, for the BWR, the RSS created five broad release categories. A brief description of each broad category can be found below:

- PWR Category 1 - Steam explosion in the reactor vessel with failure of the containment.
- PWR Category 2 - Core melt with failure of the radioactive removal system.
- PWR Category 3 - Core melt with partial success of the radioactive removal system.
- PWR Category 4 - Core melt with the containment not fully isolated and failure of the radioactive removal system.
- PWR Category 5 - Core melt, similar to Category 4, with partial success of the radioactive removal system.
- PWR Category 6 - Core melt through reactor vessel with success of the radioactivity removal system.
- PWR Category 7 - Core melt through reactor vessel with failure of the radioactivity removal system failure.
- PWR Category 8 - Fuel failure with isolation failure of the containment.
- PWR Category 9 - Fuel failure with the containment integrity maintained.
- BWR Category 1 - Steam explosion in the reactor vessel with failure of the containment.
- BWR Category 2 - Core melt after containment rupture with no or little internal deposition.
- BWR Category 3 - Overpressure rupture of containment with significant deposition.
- BWR Category 4 - Containment isolation failure with no rupture.
- BWR Category 5 - Fuel failure with radioactive release through the stack.

Of significance was Category 7 for PWRs, which was largely an unknown scenario in the nuclear industry. Aside from the LOCA and transient initiating events, the RSS attempted to estimate the general magnitude of risk associated with earthquakes, floods, tornadoes, accidental aircraft impact (note the effect of a deliberate crash on a nuclear power plant was not addressed), and turbine missiles. Failure associated with each of the external events was small compared to the

overall calculated risk. During the preparation of the report, the Browns Ferry fire occurred in 1975, and was commented upon as requiring further study. The RSS also noted that straightforward measures to improve fire prevention and fire fighting capabilities could significantly reduce the risk of reactor failure from a fire.

2.2.10 Comparison with Other Risks

Possibly the most controversial part of the RSS was the comparison of risks from nuclear power plant failures to other more common or extremely remote risks encountered by the general public. Among the risks used to illustrate the issue were automobile accidents, hurricanes, tornadoes, earthquakes, meteorites, airplane crashes, explosions, dam failures, fires, and industrial accidents leading to hazardous chemical releases. For chemical releases, the RSS used a generic chlorine release on a major rail line in Ohio. The closest in risk to 100 operating nuclear power plants of any of the examples illustrated in the RSS was the risk of a large meteorite impact estimated to be about 1×10^{-4} (or a 1-in-10,000 chance) that ten people being killed and about 1×10^{-7} that 10,000 people being killed.

2.2.11 RSS Results

The RSS calculated the frequency of core melt for a PWR to be 6×10^{-5} per reactor year and for a BWR to be 3×10^{-5} per reactor year. The major change in the failure frequency for PWRs from early studies (usually about 1×10^{-6}) is that prior estimates tended to ignore or downplay the small LOCAs' contribution to core melt, whereas the RSS determined that small LOCAs had the highest contribution to the overall risk. The RSS determined that the two largest contributors to BWR frequency of core melt were the failure to rapidly shut down the reactor when needed and the failure of the decay heat removal system after transient-caused shutdowns. Previous calculations and estimates had also concentrated on worst-case scenarios when determining the consequence of reactor accidents. The RSS showed that the majority of core-melt accidents would produce modest consequences, with only very small portions of the core-melt scenarios causing catastrophic offsite damage as envisioned in WASH-740 (USAEC 1957).

The RSS found that the conditional probability of containment failing, given occurrence of an accident sequence that releases radiation into the containment atmosphere, was higher than originally believed, although often with much of the radioactive material being deposited inside the containment building before the containment failure. The RSS modeling effort succeeded in producing an accurate and far more realistic result, compared to the previous efforts, by using event and fault trees; looking at the interaction of a molten core with the containment system; investigating common-cause and human failures; understanding the safety significance of support and other "non-safety" systems and structures; and determining possible problems in operation, test, and maintenance.

2.2.12 APS Review

One panel of scientists, organized by the American Physical Society (APS), criticized much of the report; especially the fatality estimates that considered only fatalities from radiation

absorbed in the first 24 h after an accident. The APS considered radioactive cesium and strontium (both with half-lives near 30 years) to be major contributors to any radioactive exposure of the population.

Other reviewers within the APS group also criticized the treatment of the ECCS in the RSS. Other groups contributed extensive comments to the RSS team as well, although the technical sophistication of some of the groups was low (Lewis et al. 1975).

When the NRC was finally established in 1975 and took the ownership of the draft RSS report, it published the report in October of 1975 in final form. The one section of the report that was most commonly read was the Executive Summary, which had two sections – a section summarizing the results and another comparing the risk associated with nuclear reactor failures with risks from other man-made events and natural occurrences along with frequently asked questions.

Using a few diagrams, the RSS effectively communicated that the risk associated with the operation of 100 nuclear power plants is much lower than the risk associated with automobiles, airplane crashes, or hurricanes. Unfortunately for the report, the Executive Summary became a controversial issue later.

The APS review recommended staying away from point estimates, but instead recommended using bounds to account for uncertainties based as much as possible on actual operating data, which was admittedly lacking during the RSS calculations. Possibly the biggest problem that APS review had with the RSS was the way that the RSS identified and carried uncertainties through the calculations. The committee identified several areas where the RSS did not address uncertainties well, including the use of models, variations between reactors, propagation of errors where assumptions were used rather than experimental data or models, assignment of uncertainties to the assumptions, and how the overall uncertainties were calculated.

2.3 Post-RSS Review and the Three Mile Island Accident

Following the RSS reviews in September 1978, the NRC withdrew its support of the RSS results and disavowed the Executive Summary, but the Commission tried to get the NRC staff to use PSA techniques in general.

While the RSS had considered a similar sequence of events for a reactor other than the Three Mile Island (TMI) nuclear power reactor, and showed that this sequence was not among the risk-significant contributors for that reactor design, the TMI accident confirmed a major RSS insight that small LOCAs are more risk-significant than large LOCAs that the NRC used as a design basis accident for worst-case LOCAs in licensing reactors. Also, the RSS pointed out the potential role of human error, which later was found to be a highly significant factor in the TMI accident when operators turned off the ECCS (despite the fact that this particular error was not considered by the RSS). As a result, the NRC had a change of heart and made the decision in part because one of the accident sequences studied in the RSS – where the pressurizer relief valve failed to close – was very similar to what actually occurred at the TMI accident, when adjusted for the differences in the reactors. That particular sequence had not been identified as a potential problem before the RSS. Subsequently, the NRC placed much greater emphasis on operator training and “human factors” in plant performance, investigating severe accidents.

The TMI reviews suggested that future reactor safety research should be consistent with priorities determined by their relative risk contributions, and should look not only at LOCAs, but also at transients. Only the RSS provided much information about relative risk contributions of accident scenarios. The TMI underlined the need to be cognizant of the fact that operators were running the nuclear power plant, and that a “mindset” down-playing the role of humans in the safety process existed.

2.4 Post-TMI Accident and Revival of the Use of PSA

The NRC also initiated research on steam explosions under various conditions, possible interactions between a molten core and the underlying concrete, and study of the basic processes involved with release of radioactive materials from molten fuel.

During the period of 1979–1982, the NRC undertook two sets of follow-up PSA studies. The Reactor Safety Study Methodology Application Program (RSSMAP) to apply the RSS methodology to additional reactor designs and the Interim Reliability Evaluation Program (IREP) were a planned multi-plant reliability evaluation program to develop and standardize the reliability methodology involved in performing reliability and safety studies. The IREP conceived by the NRC in accordance with the action plan developed as a result of the TMI-2 accident (USNRC 1980a) was a pilot study with a scaled-up evaluation of an additional six plants. Recognizing the lack of any formal guiding documents to perform PSAs, an effort to develop such documents was proposed by the American Nuclear Society (ANS) and the Institute for Electrical and Electronics Engineers (IEEE) to the NRC and initiated in 1983. The subsequent efforts resulted in the publication of a monumental guidebook for the performance of PSA, i.e., NUREG/CR-2300 (USNRC 1983).

In the early 1980s, the NRC relied on PSA techniques in addressing a few of its unresolved safety issues involving beyond DBAs. The most notable were the Anticipated Transients Without Scram (ATWS) and Station Blackout rules. The so-called backfit rule, which attempted to remedy some of the safety concerns that surfaced following the TMI accident, was also addressed with the help of the PSA techniques.

In addition, the risk significance of incidents reported to the NRC by the plant owners in the so-called Licensee Event Reports (LERs) was analyzed using the PSA method under the Accident Sequence Precursor (ASP) program. In this study the conditional probability of core melt due to the occurrence of these incidents was estimated by viewing them as “precursors” to severe accidents. The early precursor studies received a lot of negative publicities because they predicted rather higher conditional probability of core melt than was anticipated. The controversy diminished as the methods for accounting for these precursor events improved in the subsequent studies.

Parallel to the NRC’s efforts related to PSAs, during the early- and mid-1980s, several plant owners completed PSAs of their own to facilitate technical upgrades or characterize risk to local populations. When the PSAs for Zion and Indian Point 2 and 3 were published in 1981 and 1982, they showed the risk associated with earthquakes and fires was not negligible, as was concluded in the RSS, but quite significant requiring further study. However, all the industry-supported studies confirmed the general insights of the RSS. Furthermore, the studies focused on more advanced methodologies to determine the uncertainties more systematically than the RSS’s approach. In the meantime, the nuclear industry continued to improve PSA techniques

(for example, in modeling common cause failures), and undertook additional PSAs in support of their licensing efforts (e.g., the Seabrook Station PSA effort in 1982–1983).

2.5 Safety Goals

Subsequent to the TMI accident and the Kemeny Commission's report (Kemeny et al. 1979), the ACRS of the US NRC started an extensive debate, public workshops, and meetings, which led to the release of the NRC's policy statement establishing qualitative safety goals and associated quantitative health objectives to be used for measuring the attainment of these goals (USNRC 1986). The policy statement published in 1986 was intended to come to grips with the integration of the quantitative assessment of risk into the regulatory system. During the deliberations by the ACRS, the RSS methodology was the clearest approach to measure the quantitative safety goals proposed. The primary issue for the NRC in developing safety goals was how to use the PSA techniques to help articulate a level of acceptable risk, in other words, to define "how safe is safe enough."

The policy statement proposed two safety goals and associated Quantitative Health Objectives (QHOs) to articulate levels of acceptable risk, which later served as the de facto guidelines for using PSA results in regulation. The goals provided indices for the level of "public protection which nuclear plant designers and operators should strive to achieve." The goals meant to provide additional guidance to the NRC staff for regulatory decision-making.

Two safety goals introduced by the NRC were stated in terms of public health risk – one addressing individual risk and the other addressing societal risk. The risk to an individual is based on the potential for death resulting directly from a reactor accident – that is, a prompt fatality. The societal risk is stated in terms of nuclear power plant operations as opposed to accidents alone, and addresses the long-term impact on those living near the plant. The goals were expressed in qualitative terms, perhaps, so that the philosophy could be understood. The NRC also expressed the qualitative goals for the safety of nuclear power plants in terms of individual and societal "quantitative health objectives." The quantitative goals indirectly impacted the NRC's regulations, as the goals provided indices as to the level of "public protection which nuclear plant designers and operators should strive to achieve." They were also meant to provide additional guidance to the NRC staff as part of their regulatory decision-making process. While the safety goals provided a metric to address the question of "how safe is safe enough," practical implementation of the NRC's guidance proved to be difficult because of the large uncertainties involved in the calculation of risk (Meserve 2001).

Therefore, the NRC observed that implementation of the safety goals using subsidiary objectives that achieve the same intent as the quantitative health objectives, but do not involve as much complexity, can be useful in making regulatory decisions (USNRC 2001). These subsidiary objectives anchor, or provide guidance, on an appropriate DID philosophy that balances accident prevention and mitigation. In this light, it is indicated that a core damage frequency (CDF) of less than 1 in 10,000 per year of reactor operation is a very useful subsidiary benchmark in making judgments about that portion of regulations that are directed to accident prevention. Similarly, a large early release frequency (LERF) of less than 1 in 100,000 years is a useful subsidiary benchmark to help ensure a proper balance between prevention and mitigation. These considerations later evolved into the "benchmark" values of 1×10^{-4} /year for CDF and 1×10^{-6} /year for large release frequency (LRF) (USNRC 2007d). In addition, the design is

required by the NRC to meet a containment performance goal, which includes: (1) a deterministic goal that containment integrity be maintained for approximately 24 h following the onset of core damage for the more likely severe accident challenges and (2) a probabilistic goal that the conditional containment failure probability (CCFP) be less than approximately 0.1 for the composite of all core damage sequences assessed in the PSA.

2.6 NUREG-1150 Studies

In 1986, the NRC started work on what would become NUREG-1150, “Severe Accident Risks: An Assessment for Five US Nuclear Power Plants,” (USNRC 1980b) which was essentially an update of the RSS, with 10 more years’ additional operating experience, PSA knowledge, and methods gained following the RSS release (USNRC 1980b).

NUREG-1150 was published in final form in December 1990, following a long and extensive review process, both internally within the NRC, and also by the ANS and the IAEA. This study was the most important step forward in using probabilistic techniques in safety assessments following the release of the RSS; several areas of safety, such as mechanisms of failure and potential large loads, were investigated.

NUREG-1150 showed that the risks of severe accidents were lower than those calculated in the RSS, primarily through the use of a larger database and more sophisticated models. Furthermore, the estimation of the lower risks in NUREG-1150 as compared to the RSS results from the implementation of hardware modifications and procedural improvements at some of the plants during the period of about 15 years since the RSS.

2.7 IPE and IPEEE

To make the risk technology and methods available to the industry, the NRC issued Generic Letter 88–20 (USNRC 1988), “Individual Plant Examination for Severe Accident Vulnerabilities,” in November 1988. This letter acknowledged that each nuclear power plant is unique and may have plant-specific vulnerabilities. The NRC required each plant owner:

1. To develop an appreciation of severe accident behavior.
2. To understand the most likely severe accident sequences that could occur at its plant.
3. To gain a better quantitative understanding of the overall probabilities of core damage and fission product releases.
4. If necessary, to reduce the overall frequency of core damage and fission product releases by modifying, where appropriate, hardware and procedures that would help prevent or mitigate severe accidents.

The individual plant examination (IPE) laid out the process for each plant owner to gain experience with PSA by using its own staff as much as possible to perform the examination. Furthermore, the Generic Letter gave several additional benefits for performing PSAs – support for licensing actions, license renewals, risk management, and integrated safety assessment.

In Generic Letter 88–20, the NRC discussed what a PSA was and how the industry could use it in the future. As a result of the Generic Letter, 74 PSAs with varying degrees of detail, representing 106 US nuclear power plants were completed by 1992. Each of the PSAs looked at the reactor core damage frequency and the large early release frequency, giving the utilities

appreciation for PSA methods and a method of tracking the improvements made on the reactors in terms of risk abatement and cost-effectiveness.

In June 1991 when the IPE program was near completion, the NRC issued Supplement 4 to Generic Letter 88-20 (USNRC 1991), “Individual Plant Examination of External Events (IPEEE) for Severe Accident Vulnerabilities.” This supplement was published to require the nuclear industry to look into potential vulnerabilities to severe accidents due to externally initiated events, including seismic events, internal fires, high winds, floods, and other events involving those related to transportation and nearby facilities. The NRC received 70 IPEEE submittals covering all operating US nuclear reactors.

Similar to the IPE program, many useful perspectives were obtained from the IPEEE program especially with respect to the plant-specific vulnerabilities and capabilities in connection with externally initiated events. Although these perspectives were primarily qualitative, quantitative results such as fire area CDFs were also produced from the program (USNRC 2002a).

2.8 NRC’S PRA Policy Statement

As a direct outcome of the nuclear industry’s knowledge of PSA methods, results and uses gained through their IPE studies, some industry leaders began to lobby the NRC commissioners and staff in 1992–1993 to base some of their regulatory and enforcement efforts on PSA results, tools, and techniques. In the mean time, a law called the “Government Performance and Results Act” (GPRA) was passed by the US Congress in 1993. One objective of that law is to “improve federal program effectiveness and public accountability by promoting a new focus on results, service quality, and customer satisfaction.”

In response to the GPRA, federal agencies, including the NRC, developed strategies and plans for achieving that objective. In its Strategic Plan, the NRC is committed to move toward risk-informed and performance-based regulation. As a result, when the NRC proposes a new regulation, the alternatives considered must include a performance-based alternative that enhances the focus on the effectiveness of the agency’s regulatory programs.

The “PRA Policy Statement” (USNRC 1995) formalized the Commission’s commitment to risk-informed regulation (RIR) through the expanded use of PSA, which included among others:

The use of PRA technology should be increased in all regulatory matters to the extent supported by the state of the art in PRA methods and data, and in a manner that complements the NRC’s deterministic approach and supports the NRC’s traditional DID philosophy.

The policy statement also encouraged:

- Use of sensitivity studies, uncertainty analyses, and importance measures associated with PSA.
- Realistic evaluations of PSA as practicable.
- Availability of data used in the PSA for public review.
- Appropriate consideration of uncertainties in making regulatory judgments especially in connection with the safety goals and subsidiary numerical objectives.

This policy statement affirmed the NRC’s belief that PSA methods can be used to derive useful insights, perspectives, and general conclusions as a result of an integrated and comprehensive

examination of the design of nuclear facilities, facility response to initiating events, and also the expected interactions among facility structures, systems, and components and between the facility and its operating staff.

2.9 EPRI's PSA Applications Guide

In the side of industry, the Electric Power Research Institute published “PSA Applications Guide” in 1995 to help the industry formalize decision-making processes using PSAs (EPRI 1995). The EPRI guide developed by a group of industry experts at the request of the Nuclear Energy Institute (NEI) provided a tool to the utilities to help focus resources more effectively on subjects of true safety significance. Thus the guide represented opportunities to utilities for enhancing safety in a cost-effective manner and provided the basis for modifying plant configurations, operation, or maintenance practices in order to reduce operation and maintenance (O&M) costs without compromising safety.

In the EPRI guide the PSA applications were grouped into two broad categories: evaluation of risk significance and risk-based prioritization or ranking. The first application category primarily based on the evaluation of risk significance includes:

- Technical specification improvements
- Backfit evaluations
- Plant change assessments
- In-service test and inspection improvements
- Design option studies
- Significant event evaluations
- Justifications for continued operation
- Evaluation of inspection findings
- Evaluation of equipment out-of-service
- Evaluation of nonroutine maintenance at power
- Generic issue evaluations

On the other hand, the second category where the decision making is mostly based on the risk-based prioritization or ranking includes:

- Prioritization of plant changes
- Prioritization of test requirements
- Identification of risk significant SSCs
- Risk-based inspection and testing guidance
- Maintenance prioritization
- Procedure/training improvement programs

The EPRI guide also provided quantitative criteria to be used along with the results of qualitative review for an integrated decision making. The quantitative criteria consisted of screening criteria for permanent changes in licensing basis (e.g., plant hardware or procedural modification) and criteria for overall risk significance determination. The screening criteria for permanent changes represented a kind of industry consensus until the risk acceptance criteria were developed by the NRC as part of Regulatory Guide 1.174 discussed below.

■ **Table 2**

Criteria for Risk Significance Determination (EPRI 1995)

Risk importance measure	Criteria
Risk Reduction Worth (RRW)	
System level	>1.05
Component level	>1.005
Fussell-Vesely Importance (FV)	
System level	>0.05
Component level	>0.005
Risk Achievement Worth (RAW) (Component/train level)	>2

➤ **Table 2** shows the criteria for risk significance determination recommended in the EPRI guide. The risk significance is measured in terms of importance measures consisting of Fussell-Vesely Importance (FV), Risk Achievement Worth (RAW), and Risk Reduction Worth (RRW) (Modarres 1993). The quantitative criteria in terms of these importance measures are still widely used for various PSA applications that require assessment of the degree of risk significance (i.e., importance) with respect to components, systems, or structures independent of any changes to the plant.

2.10 Guidelines for Risk-Informed Regulation

The move toward Risk Informed Regulation (RIR) was a significant transition at the NRC fueled by the premise that a reduction in unneeded expenditure of resources on matters that are not safety significant is required to make nuclear power safer. The industry welcomed RIR because it also observed that nuclear plants can be run more effectively and economically. The challenge, however, has been to accomplish this transition while maintaining the basic objectives of adequate protection of the health and safety of the public (Ahearn et al. 2001).

The key events that had a significant impact on utility decisions to make significant investments in their PSAs during this period were the issuance of Regulatory Guide 1.174 (USNRC 2002b) and associated application specific regulatory guides. Prior to these guides, industry attempts to present risk-based or risk-informed arguments to get relief from a regulation were very difficult to develop and for the NRC staff to review, due to lack of criteria for judging “how safe is safe enough,” and lack of standards for PSA quality (Fleming 2003). These factors yielded long and costly Requests for Additional Information (RAIs), RAI responses, and associated staff reviews and a high level of inconsistency in acceptance criteria. For the first time in these regulatory guides, the NRC provided clear criteria for the review of risk-informed changes to the licensing basis including quantitative risk acceptance guidelines discussed below.

The application specific regulatory guides initially published in 1988 include:

- RG 1.175 for in-service testing (USNRC 1998b)
- RG 1.176 for graded quality assurance (withdrawn in 2002)
- RG 1.177 for technical specifications (USNRC 1998c)
- RG 1.178 for in-service inspection of piping (USNRC 2003b)

RG 1.174 (USNRC 2002b) is the basic guideline for risk-informed decision making, and as such, is supposed to be used along with the regulatory guide specifically tailored to a given application.

The request for risk-informed changes in licensing basis by a utility will be evaluated in accordance with the following principles of RG 1.174 (► Fig. 1):

1. The proposed change meets the current regulations.
2. The proposed change is consistent with the DID philosophy.
3. The proposed change maintains sufficient safety margins.
4. When proposed changes result in an increase in core damage frequency or risk, the increases should be small and consistent with the intent of the Commission's Safety Goal Policy Statement.
5. The impact of the proposed change should be monitored using performance measurement strategies.

Principle 1 requires that current regulations be met. Principles 2 and 3 represent deterministic evaluation of DID and safety margins. Principle 4 represents risk evaluation of the proposed changes where risk acceptance criteria defined in RG 1.174 are used in lieu of the safety goals. Principle 5 ensures that no adverse safety degradation occurs because of the changes to the licensing basis.

To facilitate the risk evaluation in connection with the fourth principle above, RG 1.174 provided risk-acceptance guidelines in terms of changes in the risk metrics of CDF and LERF

■ Figure 1

Principles of risk-informed integrated decision making for licensee-initiated request for risk-informed changes in licensing basis (USNRC 2002b)

resulting from the proposed change in licensing basis as depicted in ➤ [Figs. 2](#) and ➤ [3](#), respectively. PSA results are used in this decision-making process in two ways – to assess the overall baseline CDF/LERF of the plant and to assess the CDF/LERF impact of the proposed change.

It should be noted herein that risk insights will be used as one of the inputs for the integrated decision making process. Other inputs include the results of deterministic evaluation as to the maintenance of DID principle and sufficient safety margins. Furthermore, RG 1.174 requires the applicant to develop and implement a performance-monitoring

■ Figure 2

Acceptance guidelines for core damage frequency (CDF) (USNRC 2002b). The analysis will be subject to increased technical review as indicated by the darkness of the shading of the figure. In the context of the integrated decision making, the boundaries between the regions should not be interpreted as being definitive; the numerical values associated with defining the regions in the figure are to be interpreted as indicative values only

■ Figure 3

program to ensure that no adverse safety degradation occurs because of the changes to the licensing basis.

In addition, also notable is that possibly the greatest benefit that the NRC has found in the use of PSAs by utilities is that it has required the utilities to write down all the assumptions involved in reactor operation and safety systems. Prior to PSAs, many of the assumptions would never be explicitly stated in technical specifications (TS) or other design documents. By stating the assumptions explicitly, the utility could gain a better understanding of the function of the reactor and its safety systems.

2.11 Reactor Oversight Process

Continuous evaluation of the operational safety of nuclear power plants is the responsibility of both the nuclear industry and the regulatory authority. In the USA, the regulatory process of overseeing the safety performance of operating plants is called Reactor Oversight Process (ROP). The ROP revamped its inspection, assessment, and enforcement programs for nuclear power plants, and the new process was implemented in April 2000.

➤ **Figure 4** shows the US regulatory framework to provide a basis from which to develop the new ROP. The regulatory framework for reactor oversight consists of three key strategic performance areas:

- Reactor safety
- Radiation safety
- Safeguards

■ **Figure 4**
NRC regulatory framework for reactor oversight (USNRC 2006)

■ **Figure 5**

Safety culture and crosscutting issues defined in connection with the NRC regulatory framework (Kim 2008). The three crosscutting issues (i.e., human performance, problem identification and resolution, and safety conscious work environment) are included as part of the safety culture

Within each strategic performance area are cornerstones that reflect the essential safety aspects of facility operation. These seven cornerstones of safety include:

1. Initiating events
2. Mitigating systems
3. Barrier integrity
4. Emergency preparedness
5. Public radiation safety
6. Occupational radiation safety
7. Physical protection

Satisfactory licensee performance in the cornerstones provides reasonable assurance of safe facility operation and that the NRC's safety mission is being accomplished. Each cornerstone contains inspection procedures and Performance Indicators (PIs) to ensure that their objectives are being met. The safety significance of inspection findings is evaluated by Significance Determination Process (SDP) consisting of three phases, and the performance indicator data are evaluated and integrated with the SDP results to perform an integrated risk-informed assessment of plant performance.

Also notable in the regulatory framework of the NRC are the following three crosscutting areas or issues that have been identified as “cross-cutting” and potentially impacting more than one safety cornerstone (► [Fig. 5](#)):

- Human Performance (HP)
- Safety-Conscious Work Environment (SCWE)
- Problem Identification and Resolution (P&IR) programs

Satisfactory licensee performance in the seven cornerstones of safety defined in the three key strategic performance areas provides reasonable assurance of safe facility operation such that

the NRC's safety mission is being accomplished. Also notable in the framework are the three cross-cutting areas or issues that can potentially impact more than one safety cornerstone. All these cross-cutting areas are considered as constituting "safety culture" since this term is interpreted as having very wide connotations.

These aspects of licensee performance, although not identified as specific cornerstones, generally manifest themselves as the root cause of performance problems, and therefore, are very important to meeting the NRC's safety mission. The plant performance in these cross-cutting areas is assessed either explicitly in each cornerstone area or inferred through cornerstone performance results from both PIs and inspection results.

The term "safety culture," initially coined by the International Nuclear Safety Advisory Group (INSAG) of the IAEA in INSAG-4 (IAEA 1991), used to be interpreted as having the same meaning as the SCWS. However, after a further deliberation among experts in this area, it is now used in a very wide sense as encompassing all the three cross-cutting issues and beyond. As shown in ► Fig. 5, safety culture has been characterized by the NRC as consisting of not only the nine components associated with the three cross-cutting issues, but other four components as well (USNRC 2007f).

On the other hand, note that safety culture was initially defined by INSAG-4 (IAEA 1991) as follows:

Safety culture is that assembly of characteristics and attitudes in organizations and individuals which establishes that, as an overriding priority, nuclear plant safety issues receive the attention warranted by their significance.

With this definition, safety culture is regarded by the IAEA as comprising two general components. The first is the necessary framework within an organization and is the responsibility of the management hierarchy. The second is the attitude of staff at all levels in responding to and benefiting from the framework. Therefore, we can understand that the concept of safety culture has been further expanded by the NRC as compared to the original definition by the IAEA.

2.12 Maintenance Rule

In the 1980s, the NRC became concerned about the number of transients and scrams initiated as a result of problems with balance of plant systems and components. Since most of this equipment was not addressed under existing regulations, a maintenance rule (MR) was necessary. In particular, as a result of the maintenance team inspections, the NRC decided that the need for such a rule existed (USNRC 1997a). This decision rested primarily on the conclusion that proper maintenance is essential to plant safety, and that there is a clear link between effective maintenance and safety as it relates to such factors as the number of transients and challenges to safety systems and the associated need for operability, availability, and reliability of safety equipment. In addition, good maintenance is also important in providing assurance that failures of SSCs that could initiate a plant transient are minimized. On the basis of these conclusions, a risk-informed, performance-based MR was developed addressing both safety-related and certain non-safety-related SSCs.

The MR, US 10 CFR 50.65, "Requirements for monitoring the effectiveness of maintenance at nuclear power plants," was issued in July 1991 and became effective in July 1996 following a

pilot program at nine voluntary sites to verify and validate the MR inspection procedure. The text of the rule is brief, containing the basic requirements for the activities that licensees need to accomplish to monitor maintenance effectiveness. Implementation guidance was developed by the Nuclear Management and Resources Council (NUMARC), now the Nuclear Energy Institute (NEI) (NUMARC 1993). The NRC endorsed this guideline with clarifications in Regulatory Guide 1.160 (USNRC 1997b).

The purpose of the MR is to have the utilities continuously monitor the effectiveness of maintenance to ensure:

1. Safety-related and certain non-safety-related SSCs are capable of performing their intended functions.
2. For non-safety-related equipment, failures will not occur that prevent the fulfillment of safety-related functions, and failures resulting in scrams and unnecessary actuations of safety-related systems are minimized.

In light of this purpose of the MR, it is worth noting that the TMI accident was actually initiated by a scram caused by failure in the non-safety-related secondary system. More specifically, the accident investigation team identified the following maintenance problems in the non-safety-related system (Kemeny et al. 1979; Rogovin and Frampton 1980).

- The condensate polisher effluent valves closed at the beginning of the accident on March 28, 1979. These valves had closed unexpectedly twice before under similar surveillance procedures, and again later under a related condition. The postaccident investigation indicated that valve closure was triggered by water accumulating in the control air line.
- The polisher bypass valve, if appropriately designed, could provide substantial operational margin. However, it failed to open by remote control during the accident, as it had at least once before; corrective action had not been accomplished.
- In spite of the chronic problem with resin removal from a polisher and the previous failure of opening the polisher bypass valve, a serious safety problem associated with the persistent trial of removing clogged resin from the condensate polishing system was not identified by the plant personnel.
- The maintenance work package for the condensate polishing system did not properly address the contingency measure for water intrusion into the instrument air system.
- The condensate polisher, although vital to the operation of the plant, did not receive appropriate attention in design and from assurance function, engineering, management, and management review groups.

Therefore, one can understand how vital it is to perform maintenance adequately even for non-safety-related systems. A recent study (Reason and Hobbs 2003) also pointed out that maintenance errors have been among the principal causes of several major accidents in a wide range of technologies, including the Apollo 13 oxygen tank blow-out in 1970 and the crash of a Japan Air Lines B747 into the side of Mount Osutaka in 1985 as well as the TMI accident in 1979.

The initial MR was modified in July 1999 to establish requirements for the assessment and management of risk associated with maintenance activities during both power operation and shutdown; the revised rule was implemented in November 2000. The intent of this requirement is to have the configuration risk resulting from loss of function associated with unavailable equipment be appropriately controlled from a risk management perspective.

The implementation of this configuration risk management has led to day-to-day use of plant PSA model. As a result, more emphasis is now placed on requiring the PSA model to represent the as-built, as-operated plant (at least to the extent needed to support the application) (USNRC 2007e). The configuration risk management also has something to do with the requirements of technical specifications, especially limited conditions for operation, as will be discussed later. Finally, note that the implementation of the risk-informed and performance-based MR led the US nuclear industry to make considerable improvement in the plant performance as evidenced by the reduction in the number of reactor scrams and the enhanced plant availability factor, among others.

2.13 Risk-Informed Improvement to Technical Specifications

Technical Specifications (TSs) for a nuclear power plant define limits and conditions to assure that the plant is operated in a manner that is consistent with the analyses and evaluations in the plant's Safety Analysis Report. The TSs typically comprise the following major sections: (1) safety limits, (2) limiting conditions for operation (LCOs), which include allowed outage times (AOTs) for required actions, and surveillance requirements (SRs), (3) design features, and (4) administrative controls.

As the discipline of probabilistic safety assessment matures, and the computerized PSA models, such as event trees and fault trees, become available for many nuclear plants, the PSA has been increasingly used worldwide as a tool to evaluate the risk impact associated with the TS. The recent trend to move towards RIR also encourages the use of PSA. The risk evaluation of TS requirements is primarily aimed at relaxing the unnecessarily too restrictive requirements and thereby optimizing the TS requirements. Along this line, it should also be noted that some TS requirements (e.g., surveillance tests) may have adverse impact on safety, because of their potential undesirable effects, such as occurrence of test-caused reactor trips or equipment wearout resulting from too frequent tests (Kim et al. 1994; Kim 1996). In light of the recognition of such weaknesses with the traditional TS requirements, and through the results summarized in NUREG/CR-6141 (Samanta et al. 1994), RG 1.177 (USNRC 1998c) was developed to provide guidance for a risk-informed approach to licensee-initiated TS changes.

In July 1993, the NRC issued a final policy statement on TS improvements which specifically addressed the usefulness of PSA information in strengthening the technical basis of TSs (USNRC 1993). The industry and the NRC have been since pursuing increased use of PSA in developing improvements to technical specifications. At the same time great efforts were made to facilitate the license amendment process through the Technical Specification Task Force (TSTF) Travelers, the Consolidated Line Item Improvements Process (CLIIP), and the model Safety Evaluation Report (SER) (USNRC 2000b).

On behalf of the US nuclear industry the NEI is also actively pursuing Risk-Informed Technical Specifications (RITS) initiatives for fundamental improvement to the Standard Technical Specifications (STS). Some RITS initiatives represent considerable changes to the critical elements of TS requirements, i.e., AOTs and SRs. For example, the AOT for failure of a diesel generator is allowed to be temporarily extended from 7 days up 30 days, provided the configuration risk is properly managed. On the other hand, the utilities are allowed to change STIs without going through the burdensome license amendment process, if they follow the NEI guidelines already approved by the NRC (NEI 2006; NEI 2007). These initiatives have been actually implemented in several nuclear power plants of the USA.

2.14 Risk-Informed Licensing Structure for Design Safety

As there is an increasing interest in constructing or developing new nuclear power plants including advanced LWRs and non-LWRs, such as Very High Temperature Reactor (VHTR) or Sodium-Cooled Fast Reactor (SFR), sometimes called Generation-IV reactors, a question arises regarding how to ensure the design safety of these new plants. Before addressing this question, let us first look back to clearly understand what kind of method has been used thus far to ensure design safety of operating nuclear plants.

➤ *Figure 6* shows a general safety evaluation framework that has been applied in order to assure design safety of operating nuclear reactors, in other words to implement a safety case for the plants. A safety case is a documented body of evidence that provides a convincing and valid argument that the plant is safe. Such safety cases for nuclear power plants are typically included in ➤ Chap. 15 of Safety Analysis Reports (SARs). The basic concept of this high-level framework for design safety could be also applied to advanced nuclear plants like Generation-IV reactors.

A safety case is made through design basis analyses documented in SARs. The basic principle applied is that the plant should be designed such that the most frequent occurrences yield little or no adverse consequence to the public, and the improbable extreme situations, having the potential for the greatest adverse consequence to the public, shall have a low probability of occurrence.

In order to make a safety case, the applicants for design certification should first select a set of design basis events (DBEs) including AOOs and postulated accidents. Then, they have to show that even if such events occur at the plant, all the safety requirements imposed by the

■ **Figure 6**

General safety evaluation framework for a nuclear power plant (Ahn et al. 2010; Kim et al. 2010)

industry consensus standards (e.g., ANSI N18.2–1973 Standard (ANS 1973)) or the regulatory body (such as safety goals, regulatory criteria, DID, or safety margins) would be satisfied with sufficient margins.

The safety of reactor designs has been typically evaluated within a deterministic framework; for example, selection of DBAs based on deterministic arguments or engineering judgments with subsequent deterministic analysis of their effects on the plant and the public. However, due to lack of specific quantitative requirements the safety-related decisions oftentimes had to be made without clear ramifications or basis.

The probabilistic or risk-informed approach can overcome the weaknesses of the deterministic approach. However, it is generally viewed that making a decision based only on probabilistic analyses is not desirable especially due to significant uncertainties associated with such analyses. Therefore, there is a worldwide interest in developing a risk-informed licensing structure to ensure design safety of new nuclear power plants.

A simplified logic tree is presented in ► Fig. 7, which was developed to identify the attributes needed to ensure safety of advanced reactors. The top goal of “Safety Assurance of Advanced Reactors” can be satisfied if the three goals, i.e., “safe design,” “safe construction,” and “safe operation” are met.

For “Safe construction,” quality assurance program and programs such as Inspections, Tests, Analyses, And Acceptance Criteria (ITAAC) should be properly established. For “Safe Operation,” the plant should have competent reactor operators (ROs), appropriate human-machine interface (HMI), and emergency operating procedures (EOPs), and so on.

To assure safety of advanced reactors, they should be safely designed, constructed, and operated. Safe design can be ensured by making a safety case such that: (1) design basis events are properly selected and categorized so that a wide spectrum of events can be analyzed in details; (2) facts applicable to the reactors and design basis assumptions are properly made for event evaluation; and (3) acceptance criteria for the final decision making, deterministic and/or risk-based, are properly established.

■ Figure 7

Logic tree for safety assurance of advanced reactors (Ahn et al. 2010; Kim et al. 2010)

Finally, the sub-goal of “Safe design” is directly related to the design safety, the focus of the present discussion. For this, the following three sub-goals should be satisfied:

1. **Proper Selection and Categorization of Events:** As indicated earlier in connection with the general safety evaluation framework, one has to select an appropriate set of events that will be used to make the safety case. Either deterministic or risk-informed methods may be used for event selection and categorization. SFC and concurrent occurrence of loss of offsite power may be applied in developing Design Basis Events (DBEs). Examples of typical event categories include: (1) AOOs, DBAs, and BDBAs; and (2) Condition I to IV occurrences.
2. **Proper Establishment of Acceptance Criteria:** Once the impacts or consequences of the selected events on the plant and the public are analyzed using deterministic or risk-informed methods, the analysis results should be compared to a certain set of acceptance criteria. The acceptance criteria may include: (1) safety goals, Quantitative Health Objectives (QHOs), surrogate objectives in terms of Core Damage Frequency (CDF), LERF, LRF, or Conditional Containment Failure Probability (CCFP); (2) dose criteria or frequency-consequence (F–C) curve; or (3) criteria on the effects of events on key plant parameters, or criteria on the special plant phenomena such as hydrogen generation or pressurized thermal shock, etc.
3. **Proper Use of Facts and Assumptions:** As mentioned earlier, facts and assumptions will be used as evidence in making the safety case. Based on the facts applicable to the plant, the expected frequencies of initiating events and the unavailabilities of safety systems for specific situations should be analyzed together with the expected progression of the assumed events in the plant, and the expected production and behavior of the fission products once a serious accident occurs. In this regard, one can note the usefulness of PSA technique that provides a systematic procedure for detailed event sequence identification and quantification. In addition, the safety classification of SSCs also should be performed under this sub-goal as part of the assumptions.

► **Figure 7** also points out that the basic principles of DID and safety margins will continue to play a very important role in assuring design safety even for advanced nuclear plants such as Generation-IV reactors, whatever methodology is applied for safety analysis.

3 Probabilistic Safety Assessment

Probabilistic Safety Assessment (PSA) (in the US regulatory applications it is mainly referred to as Probabilistic Risk Assessment (PRA)) is a systematic procedure for investigating safety of complex systems including nuclear power plants. It is used as part of design, construction and operation. The PSAs model how human, software, and hardware elements of the plant interact with each other, assess the most significant contributors to the plant safety, and also estimates the degree or probability of loss. A formal definition proposed by Kaplan and Garrick (Kaplan and Garrick 1981) provides a simple and useful description of the elements of PSA based on risk assessment that involves addressing three basic questions:

- What can go wrong that could lead to exposure of hazards?
- How likely is this to happen?
- If it happens, what consequences are expected?

The PSA procedure involves quantitative application of the above triplets in which probabilities (or frequencies) of scenarios of events leading to exposure of hazards (such as radioactive materials from the core of the reactor) are estimated, and the corresponding magnitude of health, safety, environmental, and economic consequences for each scenario are predicted. The risk value (i.e., expected loss) of each scenario is often measured as the product of the scenario frequency and its consequences. The main result of the PSA is not the actual value of the risk computed (the so-called bottom-line number); rather it is the determination of the plant elements that substantially contribute to the risks of the nuclear plant, uncertainties associated with such estimates, and effectiveness of various risk reduction strategies available. That is, the primary value of a PSA is to highlight the plant's design and operational deficiencies and optimize resources that can be invested on improving the design and operation of the plant.

In the remainder of this section, some strengths of PSA will be presented first, and subsequently major elements of PSA will be discussed with an example PSA for a simple fire protection system.

3.1 Strength of PSA

As the formal engineering approach to safety assessment, a PSA:

1. Provides an integrated and systematic examination of a broad set of design and operational features of the nuclear power plant.
2. Incorporates the influence of plant interactions and human-system interfaces.
3. Provides a model for incorporating operating experience with the nuclear power plant and updating risk estimates.
4. Provides a process for the explicit consideration of uncertainties.
5. Permits the analysis of competing risks (e.g., of one design vs. another or of possible modifications to a plant).
6. Permits the analysis of issues associated with assumptions or data via sensitivity studies.
7. Provides a measure of the absolute or relative importance of plant's systems and components to the calculated risk value.
8. Provides a quantitative measure of overall level of health and safety for the nuclear plant.

Major errors may result from weak or absent models, or associated data of potentially important factors in the risk of the plant, including cases where: (1) initiating events with very low frequencies of occurrence, human performance models and interactions with the system are highly uncertain, and (2) common cause failures resulting from an extreme operating environment are difficult to identify and model.

3.2 Steps in Conducting a Probabilistic Safety Assessment

The following subsections provide a discussion of essential components of PSA as well as the steps that must be performed in a PSA analysis (see ► [Fig. 8](#)). The NASA PSA Procedures Guide (NASA 2002) also describes the components of the PSA. Each component of a PSA shown in ► [Fig. 8](#) is discussed below.

■ Figure 8

Components of the overall probabilistic safety assessment (PSA) process (Source: based on NASA 2002)

3.2.1 Objectives and Methodology

Preparing for a PSA begins with a review of the objectives of the analysis. Among many objectives that are possible the most common ones include design improvement, risk acceptability, decision support, regulatory oversight support, and operations and life management. An example of a set of PSA objectives may be as follows:

1. Meet a surrogate goal of less than 1×10^{-4} /year (1×10^{-5} /year based on IAEA) for core damage frequency (CDF) and a surrogate goal of less than 1×10^{-6} /year for large (radioactive) release frequency (LRF).
2. Show that containment integrity is maintained for 24 h following the onset of core damage.
3. Prove that the conditional containment frequency is 0.1 or less for the aggregate of all dominant core damage sequences.
4. Identify potential design improvement for safety-significant scenarios.
5. Determine effectiveness of various human error prevention techniques.
6. Demonstrate feasibility of defenses against common cause failures.
7. Confirm defenses against human errors.
8. Determine needed safety margins to address uncertainty.
9. Demonstrate conformance with single failure criteria.
10. List the components with the highest contribution to plant risk and safety.

Once the objectives are clarified an inventory of possible techniques for the desired analyses should be developed. The available techniques range from required computer codes to system experts and analytical experts. This, in essence, provides a road map for the analysis. The resources required for each analytical method should be evaluated, and the most effective option selected. The basis for the selection should be documented, and the selection process reviewed to ensure that the objectives of the analysis will be adequately met. See Modarres (1993) and Kumamoto and Henley (1996) for the inventory of methodological approaches to PSA.

3.2.2 Familiarization and Information Assembly

A general knowledge of the physical layout of the overall nuclear power plant, administrative controls, maintenance and test procedures, as well as barriers and subsystems, whose job is to protect, prevent, or mitigate radioactive exposure, is necessary to begin the PSA. All subsystems, structures, locations, and activities expected to play a role in the initiation, propagation, or mitigation of a hazard exposure condition must be understood in sufficient details to construct the models necessary to capture all possible scenarios. A detailed inspection of the nuclear power plant must be performed in the areas expected to be of interest and importance to the analysis. The following items should be performed in this step:

1. Major critical barriers, structures, emergency safety systems, and human interventions should be identified.
2. Physical interactions among all major subsystems (or parts of the system) should be identified and explicitly described. The result should be summarized in a dependency matrix.
3. Past major failures and abnormal events that have been observed in the plant should be noted and studied. Such information would help ensure inclusion of important applicable scenarios.
4. Consistent documentation is critical to ensure the quality of the PSA. Therefore, a good filing system must be created at the outset, and maintained throughout the study.

With the help of the designers, operators, and owners, the analysts should determine the ground rules for the analysis, the scope of the analysis, and the configuration and phases of the operation of the nuclear plant or facility to be analyzed. One should also determine the faults and conditions to be included or excluded; the operating modes of concern and the hardware configuration on the design freeze date (i.e., the date after which no additional changes in the plant, system design and configuration will be modeled). Therefore, the results of the PSA are only applicable to the plant at the freeze date.

3.2.3 Identification of Initiating Events

This task involves identifying those events (abnormal events or conditions) that could, if not correctly and timely responded to, result in hazard exposure. In a full-power plant PSA, the initiating events are typically defined as those events causing a reactor trip, automatic or manual (if the nature of the initiating event is such that it will introduce negative reactivity that stops the chain reaction in the core). The first step involves identifying sources of hazard (mostly radioactive materials) and barriers around these hazards (cladding, reactor vessel, containment as well as safety systems). The next step involves identifying events that can lead to a direct threat to the integrity of the barriers.

A nuclear power plant may operate either at power (full power or low power), or in a shutdown mode of operation (hot standby, hot shutdown, cold shutdown, or refueling). In each operational mode, specific functions are performed. Each function is directly realized by one or more safety systems by making certain actions and behaviors. These systems, in turn, are composed of more basic units (e.g., subsystems, components, hardware) that accomplish the objective of the system. As long as a system is operating within its design parameter tolerances, there is little chance of challenging the system boundaries in such a way that hazards will escape those boundaries. These operational modes are called normal operation modes.

During a normal operation mode, loss of certain functions or systems will cause the process to enter an off-normal (transient) state transition. Once in this transition, there are two possibilities. First, the state of the plant could be such that no other function is required to maintain the process in a safe condition (the term “safe” refers to a mode where the chance of core damage or radioactive release beyond the plant boundaries is negligible.) The second possibility is a state wherein other functions (and thus systems) are required to prevent exposing hazards beyond the plant boundaries. For this second possibility, the loss of the function or the system is considered an initiating event. Since such an event is related to the normally operating equipment, it is called an operational initiating event.

Operational initiating events can also apply to various modes of the plant. The terminology remains the same since, for each mode, certain equipment, people or software must be functioning. For example, an operational initiating event found during the PSA of a test nuclear reactor was Low Primary Coolant System Flow. Flow is required to transfer heat produced in the reactor to heat exchanges and ultimately to the cooling towers and the outside environment. If this coolant flow function is reduced to the point where an insufficient amount of heat is transferred, core damage could result (thus the possibility of exposing radioactive materials – the main source of hazard in this case). Therefore, another system must operate to remove the heat produced by the reactor (i.e., a protective barrier). By definition, then, Low Primary Coolant System Flow is an operational initiating event.

One method for determining the operational initiating events begins with first drawing a functional block diagram of the plant. From the functional block diagram, a hierarchical relationship is produced, with the process objective being successful completion of the desired system. Each function can then be decomposed into its subsystems and components, and can be combined in a logical manner to represent operations needed for the success of that function.

Potential initiating events are events that result in failures of particular functions, subsystems, or components, the occurrence of which causes core damage or large radioactive release into the environment. These potential initiating events are “grouped” such that members of a group require similar subsystem responses to cope with the initiating event. These groupings are the operational initiator categories.

An alternative to the use of functional hierarchy for identifying initiating events is the use of Failure Modes and Effects Analysis (FMEA) (Stamatis 2003). The difference between these two methods is noticeable; namely, the functional hierarchies are deductively and systematically constructed, whereas FMEA is an inductive and experiential technique. The use of FMEA for identifying initiating events consists of identifying failure events (modes of failures of equipment, software and human) whose effect is a threat to the integrity and availability of the hazard barriers of the system. In both of the above methods, one can always supplement the set of initiating events with generic initiating events (if known). For example, see Sattison et al. (1990) for these initiating events for nuclear reactors, and NASA PSA Procedures Guide (NASA 2002) for space vehicles.

To simplify the process, after identifying all initiating events, it is necessary to combine those initiating events that pose the same threat to barriers and require the same mitigating functions of the process to prevent hazard exposure. The following inductive procedures should be followed when grouping initiating events:

1. Combine the initiating events that directly break all barriers.
2. Combine the initiating events that break the same hazard barriers (not necessarily all).

3. Combine the initiating events that require the same group of mitigating human or automatic actions following their occurrence.
4. Combine the initiating events that simultaneously disable the normal operation as well as some of the available mitigating human, software, or automatic actions.

Events that cause transients and require other systems to operate so as to maintain hazards within their desired boundaries, but are not directly related to a hazard mitigation, protection or prevention function, are nonoperational initiating events. These nonoperational initiating events are identified with the same methods used to identify operational events. One class of such events of interest is those that are primarily external to the plant or facility. These so-called “external events” will be discussed later in more details. The following procedures should be followed in this step of the PSA:

1. Select a method for identifying specific operational and nonoperational initiating events. Two representative methods are functional hierarchy and FMEA. If a generic list of initiating events is available, it can be used as a supplement.
2. Using the method selected, identify a set of initiating events.
3. Group the initiating events having the same effect on the system; for example, those requiring the same mitigating functions to prevent hazard exposure are grouped together.

3.2.4 Sequence or Scenario Development

The goal of scenario development is to derive a complete set of scenarios that encompasses all of the potential exposure propagation paths that can lead to loss of containment or confinement of the radioactive source term (hazard), following the occurrence of an initiating event. To describe the cause and effect relationship between initiating events and their subsequent event progression, it is necessary to identify those functions (e.g., safety functions) that must be maintained to prevent loss of barriers. The scenarios that describe the functional response of the process to the initiating events are frequently displayed by event trees.

Event trees order and depict (in an approximately chronological manner) the success or failure of key mitigating actions (e.g., human actions or mitigative hardware actions) that are required to act in response to an initiating event. In PSA, two types of event trees can be developed: functional and systemic. The functional event tree uses mitigating functions as its heading. The main purpose of the functional tree is to better understand the potential scenarios of events at an abstract level, following the occurrence of an initiating event. The functional tree also guides the PSA analyst in the development of a more detailed systemic event tree. The systemic event tree reflects the scenarios of specific events (specific human actions, protective or mitigative subsystem operations or failures) that lead to a hazard exposure. That is, the functional event tree can be further decomposed to show failure of specific hardware, software or human actions that perform the functions described in the functional event tree. Therefore, a systemic event tree fully delineates the plant or nuclear facility response to an initiating event and serves as the main tool for further analyses in the PSA. For detailed discussion on specific tools and techniques used for this purpose, see (Modarres 2006).

There are two kinds of external events. First kind refers to events that originate from within the plant or nuclear facility (but outside of the physical boundary of the plant or nuclear facility), which are called internal events external to the process of the system. Events that adversely

affect the plant or overall system and occur external to its physical boundaries, but can still be considered as part of the system, are defined as internal events external to the system. Typical internal events external to the system are internal conditions such as fires from cables and other flammable items within a plant, or floods occurred due to rupture of pipes and tanks, which are part of the plant. The effects of these events should be modeled with event trees to show all possible scenarios.

The second kind of external events are those that originate outside of the plant or facility, and are called external events. Examples of external events are fires and floods that originate from outside of the system. Examples include seismic events, extreme heat, extreme drought, transportation events, volcanic events, high-wind events, terrorism, and sabotage. Again, this classification can be used in developing and grouping the event tree scenarios.

The following procedures should be followed in this step of the PSA:

1. Identify the mitigating functions for each initiating event (or group of events).
2. Identify the corresponding human actions, systems or hardware operations associated with each function, along with their necessary conditions for success.
3. Develop a functional event tree for each initiating event (or group of events).
4. Develop a systemic event tree for each initiating event, delineating the success conditions, initiating event progression phenomena, and end effect of each scenario.

3.2.5 Logic Modeling

Event trees commonly involve branch points at which a given subsystem (or event) either works (or happens) or does not work (or does not happen). Sometimes, failure of these subsystems (or events) is rare and there may not be an adequate record of observed failure events to provide a historical basis for estimating frequency of their failure. In such cases, other logic-based analysis methods such as fault trees or master logic diagrams (MLDs) may be used, depending on the accuracy desired. The most common method used in PSA to calculate the probability of subsystem failure is fault tree analysis. This analysis involves developing a logic model in which the subsystem is broken down into its basic components or segments for which adequate data exist. For more details about how a fault tree can be developed to represent the event headings of an event tree, see Modarres et al. (1999).

Different event tree modeling approaches imply variations in the complexity of the logic models that may be required. If only main functions or systems are included as event-tree headings, the fault trees become more complex and must accommodate all dependencies among the main and support functions (or subsystems) within the fault tree. If support functions (or systems) are explicitly included as event tree headings, more complex event trees and less complex fault trees will result. For more discussions on methods and techniques used for logic modeling see Modarres (2006).

The following procedures should be followed as a part of developing the fault tree:

1. Develop a fault tree for each event in the event tree heading for which actual historical failure data does not exist.
2. Explicitly model dependencies of a subsystem on other subsystems and intercomponent dependencies (e.g., common cause failures). For common cause failures, see Mosleh et al. (1988).

3. Include all potential reasonable and probabilistically quantifiable causes of failure, such as hardware, software, test and maintenance, and human errors, in the fault tree.

The following steps should be followed in the dependent failure analysis:

1. Identify the hardware, software and human elements that are similar and could cause dependent or common cause failures. For example, similar pumps, motor-operated valves, air-operated valves, human actions, software routines, diesel generators, and batteries are major components in process plants, and are considered important sources of common cause failures.
2. Items that are potentially susceptible to common cause failure should be explicitly incorporated into the corresponding fault trees and event trees of the PSA where applicable.
3. Functional dependencies should be identified and explicitly modeled in the fault trees and event trees.

3.2.6 Failure Data Collection, Analysis and Performance Assessment

A critical building block in assessing nuclear power plants risk and safety is accessibility of the reliability and availability data of the barriers which contain the radioactive source term. In particular, the best resources for predicting future availability are past field experiences and tests. Hardware, software and human reliability data are inputs to assess performance of hazard barriers, and the validity of the results depends highly on the quality of the input information. It must be recognized, however, that historical data have predictive value only to the extent that the conditions under which the data were generated remain applicable. Collection of the various failure data consists fundamentally of the following steps: collecting generic data, assessing generic data, statistically evaluating plant, facility- or system-specific data, and developing failure probability distributions using test and/or plant-specific and system-specific data. Three types of events identified during the risk scenario definition and system modeling must be quantified for the event trees and fault trees to estimate the frequency of occurrence of sequences: initiating events, component failures and human errors.

The quantification of frequencies of initiating events as well as failure probabilities of safety systems and components involve two separate activities. First, the probabilistic failure model for each barrier or component failure event must be established; then the parameters of the model must be estimated. Typically the necessary data include time of failures, repair times, test frequencies, test downtimes, common-cause failure events. Further uncertainties associated with such data must also be characterized. Kapur and Lamberson (1977), Modarres et al. (1999), and Nelson (1990) discuss available methods for analyzing data to obtain the probability of failure or the probability of occurrence of equipment failure. Also, Crow (1990) and Ascher and Feingold (1984) discuss analysis of data relevant to repairable systems. Finally, Mosleh et al. (1988) discuss analysis of data for dependent failures, Poucet (1988) reviews human reliability issues, and Smidts (1996) examines software reliability models. Establishment of the database to be used will generally involve collection of some facility-specific or system-specific data combined with the use of generic performance data when specific data are absent or sparse. For example, Refs. (IEEE 1984; DOD 1995) describe generic data for electrical, electronic, and mechanical equipment.

To attain the very low levels of risk, the systems and hardware that comprise the barriers to radioactive exposure must have very high levels of performance. This high performance is typically achieved through the use of well-designed systems with adequate margin of safety considering uncertainties, redundancy and/or diversity in hardware, which provides multiple success paths. The problem then becomes one of ensuring the independence of the paths, since there is always some degree of coupling between agents of failures such as those activated by failure mechanisms, either through the operating environment (events external to the system) or through functional and spatial dependencies. Treatment of dependencies should be carefully included in both event tree and fault tree development in the PSA. As the reliability of individual subsystems increases due to redundancy, the contribution from dependent failures becomes more important; in certain cases, dependent failures may dominate the value of overall reliability. Including the effects of dependent failures in the reliability models used in the PSA is a difficult process and requires some sophisticated, fully integrated models be developed and used to account for unique failure combinations that lead to failure of subsystems and ultimately exposure of hazards. The treatment of dependent failures is not a single step performed during the PSA; it must be considered throughout the analysis (e.g., in event trees, fault trees, and human reliability analyses).

The following procedures should be followed as part of the data analysis task:

1. Determine generic values of material strength or endurance, load or damage agents, failure times, failure occurrence rates and failures on demand for each item (hardware, human action, or software) identified in the PSA models. This can be obtained either from plant-specific or system-specific experiences, from generic sources of data, or both.
2. Gather data on hazard barrier tests, repair, and maintenance data primarily from experience, if available. Otherwise use generic performance data.
3. Assess the frequency of initiating events and other probability of failure events from experience, expert judgment, or generic sources.
4. Determine the dependent or common cause failure probabilities for similar items, primarily from generic values. However, when significant specific data are available, they should be primarily used.

3.2.7 Quantification and Integration

Fault trees and event trees are integrated and their events are quantified to determine the frequencies of scenarios and associated uncertainties in the calculation of the final risk values. This integration depends somewhat on the manner in which system dependencies have been handled. We will describe the more complex situation, in which the fault trees are dependent, i.e., there are physical dependencies (e.g., through support units of the main safety systems such as those providing motive power, proper working environment and control functions). Normally, the quantification will use a Boolean reduction process to arrive at a Boolean representation for each scenario.

Starting with fault tree models for the various systems or event headings in the event trees, and using probabilistic estimates for each of the events modeled in the event trees and fault trees, the probability of each event tree heading (often representing failure of a hazard barrier such as a safety system) is calculated (if the heading is independent of other headings). The fault trees for the main subsystems and support units (e.g., lubricating and cooling units, power units) are

merged where needed, and the equivalent Boolean expression representing each event in the event tree model is calculated. The Boolean expressions are reduced to arrive at the smallest combination of basic failures events (the so-called minimal cut-sets) that lead to exposure of the radioactive hazards. These minimal cut-sets for each of the main subsystems (that act as barriers) – that are often identified as headings on the event trees – are also obtained.

The minimal cut-sets for the event tree event headings are then appropriately combined to determine the cut-sets for the event-tree scenarios. If possible, all minimal cut-sets must be generated and retained during this process; unfortunately in nuclear power plants this leads to an unmanageably large collection of terms and a combinatorial outburst. Therefore, the collection of cut-sets are often truncated (i.e., probabilistically small and insignificant cut-sets are discarded based on the number of terms in a cut-set or on the probability of the cut-set). This is usually a practical necessity because of the overwhelming number of cut-sets that can result from the combination of a large number of failures, even though the probability of any of these combinations may be vanishingly small. The truncation process does not disturb the effort to determine the dominant scenarios since we are discarding scenarios that are extremely unlikely.

Even though the individual cut-sets discarded may be several orders of magnitude less probable than the average of those retained, the large number of them discarded may sum to a significant part of the risk. The actual risk might thus be larger than what the PSA results indicate. This can be discussed as part of the modeling uncertainty characterization. Detailed examination of a few PSA studies of nuclear power plants shows that cut-set truncation will not introduce any significant error in the total risk assessment results (Dezfuli and Modarres 1984).

Other methods for evaluating scenarios also exist that directly estimate the frequency of scenarios without specifying cut-sets. This is often done in highly dynamic systems whose configuration changes as a function of time leading to dynamic event trees and fault trees. These dynamic systems are discussed in greater details elsewhere (Chang et al. 2003; NASA 2002; Dugan et al. 1993). Employing advanced computer programming concepts, one may directly simulate the operation of parts to mimic the real system for reliability and risk analysis (Azarkhail and Modarres 2006). The following procedures should be followed as part of the quantification and integration step in the PSA:

1. Merge corresponding fault trees associated with each failure or success event modeled in the event tree scenarios (i.e., combine them in a Boolean form). Develop a reduced Boolean function for each scenario (i.e., truncated minimal cut-sets).
2. Calculate the total frequency of each sequence, using the frequency of initiating events, the probability of barrier failure including contributions from test and maintenance frequency (outage), common cause failure probability, and human error probability.
3. Use the minimal cut-sets of each sequence for the quantification process. If needed, simplify the process by truncating based on the number of terms in a cut-set or on the probability of the cut-set.
4. Calculate the total frequency for each scenario.
5. Calculate the total frequency for all scenarios included in all the event trees.

3.2.8 Uncertainty Analysis

Uncertainties are part of any assessment, modeling, and estimation. In engineering calculations we routinely ignore the estimation of uncertainties associated with failure models and

parameters, because the uncertainties are very small and more often analyses are done conservatively (e.g., by using high safety factor, design margin). Since PSAs are primarily used for decision-making and management of risk, it is critical to incorporate uncertainties in all facets of the PSA.

Also, risk management decisions that consider PSA results, must consider estimated uncertainties. In PSAs uncertainties are primarily shown in form of probability distributions. For example the probability of failure of a subsystem (e.g., a hazard barrier) may be represented by a probability distribution showing the range and likelihood of risk values.

The process involves characterization of the uncertainties associated with frequencies of initiating events, probabilities of failure of subsystems (barriers), probabilities of all event tree headings, strength or endurance of barriers, applied load or incurred damage by the barriers, amounts of source terms, consequences of exposures to radioactivity, and sustained total amounts of losses. Other sources of uncertainties are in the models used. For example the fault tree and event tree models, stress-strength and damage-endurance models used to estimate failure or capability of some barriers, probabilistic failure models of hardware, software and human, correlation between the amount of hazard exposure and the consequence, exposure models and pathways, and models to treat inter- and intra-barrier failure dependencies. Another important source of uncertainty is incompleteness of the risk models and other failure models used in the PSAs. For example, the level of detail used in decomposing subsystems using fault tree models, scope of the PSA, and lack of consideration of certain scenarios in the event tree just because they are not known or experienced before.

Once uncertainties associated with hazard barriers have been estimated and assigned to models and parameters, they must be “propagated” through the PSA model to find the uncertainties associated with the results of the PSA; primarily with the bottom-line risk calculations, and with the list of risk significant elements of the system. Propagation is done using one of several techniques, but the most popular method used is Monte Carlo simulation. The results are then shown and plotted in form of probability distributions. Steps in uncertainty analysis include:

1. Identify models and parameters that are uncertain and the method of uncertainty estimation to be used for each.
2. Describe the scope of the PSA and significance and contribution of elements that are not modeled or considered.
3. Estimate and assign probability distributions depicting model and parameter uncertainties in the PSA.
4. Propagate uncertainties associated with the hazard barrier models and parameters to find the uncertainty associated with the risk value.
5. Present the uncertainties associated with risks and contributors to risk in an easy way to understand and visually straightforward to grasp.

3.2.9 Sensitivity Analysis

Sensitivity analysis is the method of determining the significance of choice of a model or its parameters, assumptions for including or not including a safety system, physical barrier, phenomenon or hazard, performance of specific barriers, intensity of hazards, and significance of any highly uncertain input parameter or variable to the final risk value calculated. The process

of sensitivity analysis is straightforward. The effects of the input variables and assumptions in the PSA are measured by modifying them by several folds, factors or even one or more orders of magnitude one at a time, and measure relative changes observed in the PSA's risk results. Those models, variables and assumptions whose change leads to the highest change in the final risk values are determined as "sensitive." In such a case, revised assumptions, models, additional failure data, and more mechanisms of failure may be needed to reduce the uncertainties associated with sensitive elements of the PSA.

Sensitivity analysis helps focus resources and attentions to those elements of the PSA that need better attention and characterization. A good sensitivity analysis strengthens the quality and validity of the PSA results. Usually elements of the PSA that could exhibit multiple impacts on the final results, such as certain phenomena (e.g., pitting corrosion, fatigue cracking and common cause failures) and uncertain assumptions are usually good candidates for sensitivity analysis. The steps involved in the sensitivity analysis are:

1. Identify the elements of the PSA (including assumptions, failure probabilities, models, and parameters) that analysts believe might be sensitive to the final risk results.
2. Change the contribution or value of each sensitive item in either direction by several factors in the range of 2–100. Note that certain changes in the assumptions may require multiple changes of the input variables. For example a change in failure rate of similar equipments requires changing of the failure rates of all these equipments in the PSA model.
3. Calculate the impact of the changes in step 2 one-at-a-time and list the elements that are most sensitive.
4. Based on the results in step 3 propose additional data, any changes in the assumptions, use of alternative models, modification of the scope of the PSA analysis.

3.2.10 Risk Ranking and Importance Analysis

Ranking the elements of the system with respect to their risk or safety significance is one of the most important outcomes of a PSA. Ranking is simply arranging the elements of the plant based on their increasing or decreasing contribution to the final risk values. Importance measures rank hazard barrier, subsystems or more basic elements of them usually based on their contribution to the total risk of the plant or facility. The ranking process should be done with much care. In particular, during the interpretation of the results, since formal importance measures are context dependent and their meaning varies depending on the intended application of the risk results, the choice of the ranking method is important.

There are several unique importance measures in PSAs. For example, Fussell-Vesely, Risk Reduction Worth (RRW), and Risk Achievement Worth (RAW) (Modarres et al. 1999) are identified as appropriate measures for use in PSAs, and all are representative of the level of contribution of various elements of the plant as modeled in the PSA and enter in the calculation of the total risk. For example, Birnbaum importance measure represents changes in total plant risk as a function of changes in the basic event probability of one component at a time (Birnbaum 1969). If simultaneous changes in the basic event probabilities are being considered, a more complex representation would be needed.

Importance measures can be classified based on their mathematical definitions. Some measures have fractional type definitions and show changes (in the number of folds or factors) in the system total risk under certain conditions with respect to the normal operating or use condition (e.g., as is the case in RRW and RAW measures). Some measures calculate the changes in the system total risk as failure probability of hazard barriers and other elements of the system or conditions under which the plant operates change. This difference can be normalized with respect to the total risk of the plant or even expressed in a percentage change form. There are other types of measures, which account for the rate of changes in the system risk with respect to changes in the failure probability of the elements of the plant. These measures can be interpreted mathematically as partial derivative of the risk with respect to the failure probability of its elements (barriers, components, human actions, phenomena, initiating events, etc.). For example, the Birnbaum measure falls under this category.

Another important set of importance measures focus on ranking the elements of the plant based on the contributions to the total uncertainty of the risk results obtained from PSAs. This process is called “uncertainty ranking” and is different than component, subsystem, and barrier ranking. In this importance ranking the analyst is only interested to know which of the system elements drive the final risk uncertainties, so that resources can be focused on reducing important uncertainties.

There is another classification for importance measures in which they can be divided into two major categories of absolute and relative. Absolute measures are representative of fixed importance of one element of the system, independent of the importance of other elements, while relative importance expresses significance of one element with respect to weight of importance of other elements. Absolute importance can be used to estimate the impact of component performance on the system regardless of how important other elements are, while relative importance estimates the significance of the risk-impact of the component in comparison to the effect or contribution of others.

Absolute measures are useful when we speculate on improving actions, since they directly show the impact on the total risk of the system. Relative measures are preferred when resources or actions to improve or prevent failures are taken in a global and distributed manner. The risk ranking methods and their implications in failure and success domains are discussed in greater details elsewhere (Azarkhail and Modarres 2004). Applications of importance measures may be categorized into the following areas:

1. (Re)Design: To support decisions of the plant, system design or redesign by adding or removing elements (barriers, subsystems, human interactions, etc.).
2. Test and maintenance: To address questions related to the plant performance by changing the test and maintenance strategy for a given design.
3. Configuration and control: To measure the significance or the effect of failure of a component on risk or safety or temporarily taking a component out of service.
4. Reduce uncertainties in the input variables of the PSA.

The following are the major steps of importance ranking:

1. Determine the purpose of the ranking and select an appropriate ranking importance measure that has consistent interpretation for the use of the ranked results.
2. Perform risk ranking and uncertainty ranking, as needed.
3. Identify the most critical and important elements of the system with respect to the total risk values and total uncertainty associated with the calculated risk values.

3.2.11 Interpretation of Results

When the risk values are calculated, they must be interpreted to determine whether any revisions are necessary to refine the results and the conclusions. There are two main elements involved in the interpretation process. The first is to understand whether or not the final values and details of the scenarios are logically and quantitatively meaningful. This step verifies the adequacy of the PSA model and the scope of analysis. The second is to characterize the role of each element of the system in the final results. This step defines additional analyses, failure data and information that would be needed to make the risk results more useful.

The interpretation process heavily relies on the details of the analysis to see whether the scenarios are logically meaningful (for example by examining the minimal cut-sets of the scenarios), whether certain assumptions are significant and greatly control the risk results (using the sensitivity analysis results), and whether the absolute risk values are consistent with any historical data or expert opinions, if available. Based on the results of the interpretation, the details of the PSA logic, its assumptions and scope may be modified to update the results into more realistic and dependable values.

The ranking and sensitivity analysis results may also be used to identify areas where gathering more information and performing better analysis (for example by using more accurate models) is warranted. The primary aim of the process is to reduce uncertainties in the risk results.

The interpretation step is a continuous process while developing the PSA. For example it continues receiving information from the quantification, sensitivity, uncertainty, and importance analysis results and assures that such results are accurate, proper, and sufficient. The process continues until the final results can be best interpreted and used in the subsequent risk management steps.

The basic steps of the PSA results interpretation include:

1. Determine accuracy of the logic models and scenario structures, assumptions, and scope of the PSA.
2. Identify system elements for which better information would be needed to reduce uncertainties in failure probabilities and models used to calculate performance.
3. Revise the PSA and reinterpret the results until attaining stable and accurate results.

3.3 A Simple Example of PSA

Consider the fire protection system shown in  Fig. 9. This system is designed to extinguish all possible fires in a plant with toxic chemicals. Two physically independent water extinguishing nozzles are designed such that each is capable of controlling all types of fires in the plant. Extinguishing (fire suppression) nozzle 1 is the primary method of injection. Upon receiving a signal from the detector/alarm/actuator device, pump-1 starts automatically, drawing water from the reservoir tank and injecting it into the fire area in the plant. If this pump injection path is not actuated, plant operators can start a second injection path manually. If the second path is not available, the operators will call for help from the local fire department (fire brigade), although the detector also sends a signal directly to the fire department. However, due to the delay in the arrival of the fire brigade, the magnitude of damage would be higher than it would be if the local fire suppression nozzles were available to extinguish the fire.

■ **Figure 9**
A fire protection system

This system is designed to extinguish all possible fires in a plant with toxic chemicals. Two physically independent water extinguishing nozzles are designed such that each is capable of controlling all types of fires in the plant. Extinguishing (fire suppression) nozzle 1 is the primary method of injection. Upon receiving a signal from the detector/alarm/actuator device, pump-1 starts automatically, drawing water from the reservoir tank and injecting it into the fire area in the plant. If this pump injection path is not actuated, plant operators can start a second injection path manually. If the second path is not available, the operators will call for help from the local fire department (fire brigade), although the detector also sends a signal directly to the fire department. However, due to the delay in the arrival of the fire brigade, the magnitude of damage would be higher than it would be if the local fire suppression nozzles were available to extinguish the fire.

Under all conditions, if the normal off-site power is not available due to the fire or other reasons, a local generator would provide electric (AC) power to the pumps. The power to the detector/alarm/actuator system is provided through the batteries, which are constantly charged by the off-site power. Even if the AC power is not available, the DC power provided through the battery is expected to be available at all times. The manual valves on the two sides of pump-1 and pump-2 are normally open, and only remain closed when they are being repaired. The entire fire system and generator are located outside of the fire compartment, and are not affected by an internal fire. Assuming all the preliminary steps of familiarization and choice of the PSA methodology have been accomplished, the remaining steps of the PSA for this situation can be performed as explained below:

Identification of Initiating Events

In this step, all equipment (e.g., cables, electric and control cabinets, pumps, ventilation system) and events (e.g., transient materials and fuel subject to ignition, hot works, and human error) that could cause fire in the reactor compartment (room), must be identified. These should include equipment malfunctions, human errors, and facility conditions. The frequency of each

event should be estimated. There are a number of sources of data that can be used to estimate the frequency of fire, e.g., NUREG/CR-6850 (EPRI 2005). Assuming that all events would lead to the same magnitude of fire, the ultimate initiating event would be occurrence of a fire, the frequency of which is the sum of the frequencies of the individual fire-causing events. Assume in this example the frequency of fire is estimated at 1×10^{-6} per year. Since fire is the only challenge to the plant in this example, we end up with only one initiating event. However, in more complex situations, a large set of initiating events can be identified, each posing a different challenge to the plant.

Scenario Development

In this step, we should explain the cause and effect relationship between the fire and the progression of events following the occurrence of fire. We use the event-tree method to depict this relationship. Generally, this is done inductively, and the level of detail considered in the event tree is somewhat dependent on the analyst. Two protective measures as hazard barriers have been considered in the event tree shown in ➤ Fig. 10: on-site protective measures (on-site pumps, tanks, etc.), and off-site fire department measures. The selection of these protective barriers is based on the fact that availability or unavailability of the on-site or off-site measures would lead to different damage states.

Logic Modeling

In this step, we should identify all failures (equipment or human) that lead to failure of the event-tree headings (on-site or off-site protective measures). For example, ➤ Fig. 11 shows the fault tree developed for the On-Site Fire Protection System. In this fault tree, all basic events that lead to the failure of the two independent paths are described. Note that the detector alarm actuator (DAA), the electric power to the pumps, and the water tank are shared by the two paths. Clearly these are considered as physical dependencies. This is taken into account in the quantification step of the PSA. In this tree, all external event failures and passive failures are neglected. This tree is simple because it only includes all failures not leading to an on-time response from the local fire department. Similarly an off-site fault tree model can be developed as shown in ➤ Fig. 12.

It is also possible to use a master logic diagram (MLD) for system analysis. An example of the MLD for this problem is shown in ➤ Fig. 13. However, for this example only the fault trees are used in the PSA, although the MLD can also be used.

■ Figure 10
Scenarios of events following a fire using the event-tree methods

■ **Figure 11**
Fault tree for the on-site fire protection system failure

Failure Data Analysis

It is important at this point to calculate the probabilities of the basic failure events described in the event trees and fault trees. As indicated earlier, this can be done by using system-specific data, generic data, or expert judgment. ➤ [Table 3](#) describes the data used and their sources. It is assumed that at least 10 h of operation is needed for the fire to be completely under control.

Quantification

To calculate the frequency of each scenario defined in ➤ [Fig. 10](#), we must first determine the cut-sets of the two fault trees shown in ➤ [Figs. 11](#) and ➤ [12](#). From this, the cut-sets of each scenario are determined, followed by calculation of the probabilities of each scenario based on the occurrence of one of its cut-sets.

These steps are described below.

1. The cut-sets of the On-Site Fire Protection System Failure can be obtained by representing the fault tree of ➤ [Fig. 11](#) in terms of a Boolean equation for the top event, i.e., ONS, and then, reducing it by Boolean algebra (Modarres et al. 1999). These cut-sets are listed in ➤ [Table 4](#). Although several different types of common cause failure (e.g., among multiple valves or between the two pumps) can be considered, it is assumed that the potential for common cause failure exists only between the two pumps for simplicity. Cut-set number 24 represents the common cause failure of pumps 1 and 2.

■ Figure 12
Fault tree for the off-site fire protection system failure

2. The cut-sets of the Off-Site Fire Protection System Failure are similarly obtained and listed in ➤ Table 5.
3. The cut-sets of the three scenarios are obtained using the following Boolean equations representing each scenario:

$$\text{Scenario-1} = F \cdot \overline{\text{ONS}}$$

$$\text{Scenario-2} = F \cdot \text{ONS} \cdot \overline{\text{OFS}}$$

$$\text{Scenario-3} = F \cdot \text{ONS} \cdot \text{OFS}$$

4. The frequency of each scenario is obtained using data listed in ➤ Table 3. These frequencies are shown in ➤ Table 6.
5. The total frequency of each scenario is calculated using the rare event approximation. These are also shown in ➤ Table 6.
6. Consequences. In the scenario development and quantification tasks, we identified three distinct scenarios of interest, each with different outcomes and frequencies. The consequences associated with each scenario should be specified in terms of both economic and/or human losses. This part of the analysis is one of the most difficult for several reasons.
 - Each scenario poses different hazards and methods of hazard exposure, and requires careful monitoring. In this case, the model should include the ways the fire can spread through the plant, how people can be exposed, evacuation procedures, the availability of protective clothing, etc.

■ Figure 13

Mater logic diagram for the entire fire protection system

- The outcome of the scenario can be measured in terms of human losses. It can also be measured in terms of financial losses, i.e., the total cost associated with the scenario. This involves assigning a dollar value to human life or casualties, which is a source of controversy.

Suppose a careful analysis of the spread of fire and fire exposure is performed, with consideration of the above issues, and ultimately results in damages measured only in terms of economic losses to the local fire compartment and beyond. These results are shown in

➤ [Table 7](#).

Table 3
Sources of data and failure probabilities

Failure event	Plant-specific experience	Generic data	Probability used	Comments
Fire initiation frequency	No such experience in 10 years of operation	Five fires in similar plants. There are 70,000 plant-years of experience	$F = 5/70,000$ $= 7.1 \times 10^{-4}/\text{year}$	Use generic data
Pump 1 and Pump 2 failure	Four failures of two pumps to start in a single year were observed. Each pump has an average of ten demands (tests) per month. Repair time takes about 2.5 h. No experience of failure to run	Failure to run $= 1 \times 10^{-5}/\text{h}$	$\frac{4}{2(12)(10)}$ $= 1.7 \times 10^{-2}/\text{demand}$ Unavailability $= 1.7 \times 10^{-2} + \frac{2.5(4)}{8760}$ $= 1.8 \times 10^{-2}/\text{demand}$ $P_1 = P_2 = 1.8 \times 10^{-2}$	Failure to start is facility-specific. For failure to run, use generic data
Common cause failure between Pump 1 and Pump 2	No such experience	Using the β -factor method, $\beta = 0.1$ for failure of pumps to start	Unavailability due to common cause failure: $\text{CCF} = 0.1 \times 1.8 \times 10^{-2}$ $= 1.8 \times 10^{-3}/\text{demand}$	Assume no significant common cause failure exists between valves and nozzles
Failure of isolation valves	Two failure to leave the valve in open position following Ten pump tests in 1 year	Not used	$V_{11} = V_{12} = V_{21} = V_{22}$ $= \frac{2}{10(12)(4)}$ $= 4.2 \times 10^{-3}/\text{demand}$	Facility-specific data used
Failure of nozzles	No-such experience	$1 \times 10^{-5}/\text{demand}$	$N_1 = N_2$ $= 1.0 \times 10^{-5}/\text{demand}$	Generic data used
Diesel generator failure	Three failures in tests. 40 h of repair per year	3.0×10^{-2} demand $3.0 \times 10^{-3}/\text{h}$	Failure on demand $= \frac{3}{12(10)}$ Failure on demand $= 2.5 \times 10^{-2}/\text{demand}$ Failure on run $= 3.0 \times 10^{-3}/\text{h}$ Total failure of DG $= 2.5 \times 10^{-2} + 3.0 \times 10^{-3} = 5.5 \times 10^{-2}$	Facility-specific data used for demand failure
Loss of off-site power	No experience	0.1/year	OSP $= 0.1 \times \frac{10}{8760}$ $= 1.1 \times 10^{-4}/\text{demand}$	Assume 10 h of operation for fire extinguisher and use generic data

■ **Table 3 (continued)**

Failure event	Plant-specific experience	Generic data	Probability used	Comments
Failure of detector alarm actuator (DAA)	No experience	No data available	DAA = 1×10^{-4} /demand	This estimate is based on expert judgment
Failure of operator to start Pump 2	No such experience	Using THERP	OP1 = 1×10^{-2} /demand	The THERP method is discussed in (Swain and Guttman 1983)
Failure of operator to call the fire department	No such experience	1×10^{-3}	OP2 = 1×10^{-3} /demand	This is based on experience from no response to similar situations. Generic probability is used
No or delayed response from fire department	No such experience	1×10^{-4}	LFD = 1×10^{-4} /demand	This is based on response to similar cases from the fire department. Delayed/no arrival is due to accidents, traffic, communication problems, etc.
Tank failure	No such experience	1×10^{-5}	T = 1×10^{-5} /demand	This is based on data obtained from rupture of the tank or insufficient water content

7. Risk Calculation and Evaluation. Using values from ► [Table 7](#), we can calculate the risk associated with each scenario. These risks are shown in ► [Table 8](#). Since this analysis shows that the mean risk due to fire is rather low, uncertainty analysis is not very important. However, a certain method like Monte Carlo simulation could be used to estimate the uncertainty associated with models and parameters (e.g., failure rates) of each component and the fire-initiating event if necessary. The uncertainties should be propagated through the cut-sets of each scenario to obtain the uncertainty associated with the frequency estimation of each scenario. The uncertainty associated with the consequence estimates can also be obtained. When the uncertainties associated with the consequence

Risk associated with each scenario

Scenario number	Economic consequence (expected loss)
1	$(7.1 \times 10^{-4})(\$1,000,000) = \710.000
2	$(2.5 \times 10^{-6})(\$92,000,000) = \230.000
3	$(8.6 \times 10^{-11})(\$210,000,000) = \0.018

■ Figure 14

Risk profile of the fire protection system

largely deterministic, it is expected that PSA methods will be increasingly and more widely used to support decision making for safety along with key deterministic philosophies such as DID or safety margin. The hybrid approach of deterministic and probabilistic safety analysis methods are applied for various purposes, including: certifying nuclear plant design, preparing and evaluating requests for construction/operation permits or license amendments, assessing operational events that occur at power or during plant shutdown, reducing unnecessary operational burden, addressing security issues, etc.

The PSA methods have been considerably improved since the landmark WASH-1400 study (USNRC 1975). However, the following issues in particular should be addressed in the future to corroborate the usefulness of the probabilistic methods (USNRC 2003c; Fleming 2003):

- Model-to-plant fidelity issues including multi-unit site modeling issues, digital-systems modeling issues, and lack of detailed review by plant personnel to ensure fidelity with plant systems, operator actions, etc.
- PSA scope issues, i.e., use of limited-scope PSAs in risk-informed applications without sufficient justification.
- Lack of completeness within the specified scope, e.g., missing consideration of system interactions or particular accident scenarios.
- Lack of, or inadequate, treatment of uncertainties.
- Quantification issues (e.g., error due to cut-set truncation).
- Lack of treatment of aging effects.
- Issues with the use and interpretation of risk metrics or importance measures.
- Lack of incorporation of operating experience in PSAs.
- Inadequate treatment of common-cause failures.
- Lack of coherence between probabilistic and deterministic safety approaches.

Finally, it is also notable that a number of works have been performed to enhance the event tree/fault tree methodology generally employed in the PSAs by developing “dynamic methodologies” to treat various time-dependent interactions; namely, time-dependent interactions between plant physical processes (e.g., heatup, pressurization) and triggered or random logical events (e.g., valve openings, pump startups) as an accident evolves, or the time-dependent interactions between the plant and its human operators (Aldemir and Siu 1996). Progress is being made in the area of dynamic process system reliability, and safety analysis, although key problems still remain, for example, in: (1) creating realistic representations of overall system behavior, such as the treatment of human operators (individuals and teams) and software control systems; (2) establishing criteria to specify when exactly dynamic analyses should be employed, since such analyses require significantly more resources than conventional, static analyses.

Abstract: Effective field modeling of two-phase flow has provided a critical part of the foundation upon which light water (power) reactor technology was made to rest some 20–30 years ago. We can envision a similarly significant role in the future as simulation capabilities are poised to meet new kinds of practical demands at the interplay between economics, safety assurance, and regulatory needs. These new demands will require better predictive reliability for larger departures from past practices, and this in turn will require strengthening of the scientific component along with translating past empiricism into more and more fundamental terms. In this perspective, the mathematical formulation of the effective field model, as well as the numerical implementation of this formulation needs to be revisited and reassessed. Helping respond to this need is the purpose of this chapter.

We delineate a conceptual framework for addressing prediction of multiphase flows at the three-dimensional, phase distribution level. This is in terms of a local, disperse system description (bubbles/drops in a continuous liquid/vapor phase). The requirement that follows is a well-posed formulation and a high-fidelity numerical treatment that allows capturing of shocks and contact discontinuities over all (relative) flow speeds, consistently with what is physically allowable according to the density ratios involved — in particular, high relative Mach numbers for droplet/particle flows. The importance of inviscid interactions (between the phases) in this context is highlighted.

The scope is for disperse-phase volume fractions up to about 20% as pertinent to fluid-fluid systems. This provides the basis for addressing phase transitions through coalescence as this process becomes significant at still higher volume fractions. The theoretical framework provides also the basis for extensions (outlined only in general terms here) to the high-volume fractions pertinent to dense solid-particle systems. The computational approach is readily applicable to both these extensions.

A general disperse system formulation is derived by means of a new, “hybrid” method that incorporates features of a statistical approach and reveals more clearly the nature of phase interactions at the individual particle scale. Moreover in this manner the formulation lends itself to elaboration of the constitutive treatment by means of numerical simulations (based on the direct solution of the Navier-Stokes equations) resolved at the particle scale. The formulation is exemplified by successive applications to various increasingly complex situations, starting with non-dissipative systems, where one or the other phase may be incompressible. At each step we examine the hyperbolic character of the system of equations, and we include consideration of high (relative) Mach numbers. The basic constitutive treatment concerns pseudo-turbulent fluctuations of the continuous phase, and the resulting systems of equations are fully closed and hyperbolic even in their non-dissipative form (ready for computation), except for a non-hyperbolic corridor around the transonic region. Results obtained are discussed in relation to formulations that form the basis of current numerical tools (codes) employed in nuclear reactor design and safety analyses (mostly addressing bubbly flows), as well as formulations found in other contexts.

This mathematical formulation is pursued further to its numerical implementation. With an emphasis on flow compressibility, we focus on capturing shocks and contact discontinuities robustly for all flow speeds and at arbitrarily high spatial resolutions. As we learn from relatively recent progress in single-phase flows, the key role is that of “up-winding” applied on the basis of a scheme that emphasizes conservative discretization. This background is briefly reviewed, culminating with a rather detailed exposition of the most recent advance in this line of development: the Advection Upstream Splitting Method (AUSM). The essential and new step here is to extend the basic ideas of the AUSM to the compressible multi-hydrodynamics

problems of interest here, and the above-mentioned EFM in particular. We also include calculations illustrative of numerical performance.

The presentation is arranged into two autonomous parts: Part I addresses the formulation of the EFM and Part II deals with the numerical implementation and testing. An overall summarization of where we stand at the completion of this work and what we see as needed future developments is provided in the following.

One basic objective was to address inviscid interactions by means of a coherent theoretical formulation and through to computational testing. In particular, we wanted to access high-fidelity simulations of the type needed to address flow regimes at all flow speeds; especially at the high relative Mach numbers pertinent to disperse particle/droplet flows. This requires that the system of equations be hyperbolic, and we wanted to achieve a solid foundation rather than adopting any of the several ad hoc constitutive models as post facto “remedying” the problem.

On theory, we begin with entropy rather than energy transport equations and we derive, consistently with thermodynamics and the momentum equations, a condition for satisfying conservation of total energy. This condition is of utmost importance showing the tight link between the conservation laws employed, and the transport equations of volume fraction and of pseudo-turbulent kinetic energies of the continuous (included) and disperse (not yet included in the derivation) phases. On this basis we demonstrate a systematic way to deduce closed systems of equations for non-dilute disperse flows, and thusly we arrive at an EFM that is hyperbolic except for a “corridor” around the transonic region. The key is a function of the disperse phase volume fraction $E(\alpha_d)$. It enters as a coefficient of the disperse phase pseudo-turbulent kinetic energy. Awaiting further definition as a function of the Mach number, by means of the type of direct simulations noted above, it is employed here throughout in its zero-Mach form. A much needed extension would also involve the pseudo-turbulent kinetic energy of the disperse phase, along with physics of dense dispersions (collisions etc.).

While terms such as those proposed previously for “interfacial pressure” and “added mass” phenomena can be identified, the complete formulation is not reducible to any of those ad hoc models. Notably, the disperse phase pressure appears nowhere in the momentum equations. Also we find that the claimed as hyperbolic, Baer-Nunziato model involves a volume fraction transport equation, which is not physically tenable for dispersions, or is it an appropriate means to dealing with ill-posedness. On the other hand, we find perfect agreement with the formulations obtained at the incompressible limit by Geurst (1985), employing a complex variational approach, and by Wallis (1989), employing a rather involved development based on potential flow theory.

On computations our objective is to capture shocks and contact discontinuities, for conditions that are within the hyperbolic regions in the Mach number space, and to explore (1) behaviors within the non-hyperbolic corridor, and (2) means of stabilization as necessary. Given the EFM development needs expressed above, it is understood that this testing in the Mach number space is strictly provisional. We begin with an adaptive mesh refinement infrastructure, and the Advection Upstream Splitting Method (AUSM), currently the method of choice for single-phase compressible flows. A key point of adaptation to our EFM is treating the pseudo-turbulent stresses within the pressure flux splitting, and ensuring that the discretization of the nonconservative terms is done in a way that satisfies propagation of contact discontinuities in uniform steady flow without disturbing the pressure field. Our approach is readily extendable to any equation of state and to adding any number of equations (volume fraction transport, multiple equations for the disperse phase for tracking multiple length scales

as may be found when the disperse phase is subject to fragmentation). The testing performed for this work was done on 1D problems only. Extending this testing to 2D and 3D problems is underway.

Testing was carried out independently with two computer codes: ARMS (all-regime multiphase simulation) and MuSiC-ARMS (Multi-scale Simulation Code-ARMS). The ARMS was built on an open access platform, the structured adaptive mesh refinement infrastructure (SAM-RAI) developed at Lawrence Livermore National Laboratory. The MuSiC-ARMS was built, more recently, on the MuSiC platform, our own specialized code, using irregular grids to “fit” areas of highest refinement (shocks, interfaces, etc.), which are embedded in a multilevel (adaptive) Cartesian mesh. This platform is also used for a DNS code, the MuSiC-SIM, and a pseudo-compressible (incompressible) code, the MuSiC-ISIM. We focus on dispersed being the heavy phase (droplet/particle flows) so as to access realistically high Mach numbers, and significant inviscid interactions.

The test cases were selected to include various kinds of Riemann problems with discontinuities in (a) Mach number only (Fitt’s problems) and (b) pressure, or pressure and disperse phase volume fraction (shock tube problems). In the Fitt’s problem case, we include parametric studies on the value of C that appears in function $E(\alpha_d)$. In addition, we consider shock wave “impact” problems on particle clouds that are either with sharp or smooth (in particle volume fraction) outer boundaries, and as part of this class also the case of dilute clouds for which we have the analytic solution for comparison. Finally, we considered the capturing of contact discontinuities in “mild” situations such as the so-called Faucet problem and the simple convection of a coherent second phase by uniform flow. The Faucet problem is well known to be failed under grid refinement in all published tests to date. The convection problem is important check of the pressure non-disturbing condition, a requirement that is hard to meet due to the non-conservative terms found in all effective field models.

The emphasis being on stability and convergence under grid refinement, all problems were carried out in the inviscid limit (no interfacial drag), and all cases passed the test except for the high pressure ratio shock tube problems where instabilities developed within the expansion wave. However, these cases were stabilized with a minimal amount of dissipation effected by adding a small amount of interfacial drag (roughly one tenth of the normal amount). These numerical results render support to the idea that, notwithstanding the “mild” non-hyperbolic corridor found in the analysis of Part I, the present effective field model is hyperbolic, and along with the numerical treatment employed they provide access to rather extreme two-phase flow conditions in a robust and accurate manner.

In an overall perspective of computational fluid dynamics, the presently offered capability is complementary to that already available through the “standard”, non-hyperbolic two-fluid model as already found in the computational frameworks of the ICE (Harlow and Amsden 1968) and SIMPLE (Patankar and Spalding 1972) methods. The special purposes aimed here are to overcome limitations in grid refinement and to approach flows where the phasic-relative velocities are high enough to introduce significant compressibility effects. Rapid advancement in hardware makes computational analysis of complex multiphase flows, even direct numerical simulations, increasingly more practical and reliable. High-fidelity/resolution techniques such as those employed here can address problems of varying time and length scales and this paves the way for actual simulations of multiphase physics at the effective field level, and even allowing a seamless analysis transitioning across regimes of multiphase flows.

PART I: EFFECTIVE FIELD FORMULATION OF MULTIPHASE FLOWS

1 Introduction and Scope I

The essence of multiphase flows is in the space-time distribution of phases and their length scales. Hence the need for an elaborated description of the Flow Regime or Flow Pattern, a topic of inquiry that began from the very first engineering efforts on the subject nearly a century ago, yet a topic of inquiry that remains largely unfulfilled (Theofanous and Hanraty 2003). Once the flow pattern is known everything else follows in a basic way. In fact all key behaviors of multiphase systems depend on the relevant flow regimes at the appropriate scale(s); for example, the limits to coolability (critical heat flux) are to be found in the microscopic flow pattern in the immediate vicinity of the heating surface, at a scale much smaller than realized previously (Theofanous et al. 2002). The fact that the design of safety systems in light water reactors has reached maturity, notwithstanding the absence of such a foundation, is owed to a large extent to a huge, comprehensively defined set of experiments over several scales up to prototypic that served to (empirically) anchor the numerical simulation tools (so-called systems codes) developed in this era (RELAP5, TRAC-BWR, and the CATHARE code that followed). Conversely, none of this would have been possible if not for the organizing principle provided by the mathematical framework (the so-called two-fluid model) at the basis of these computational tools. Indeed, it was the synergism thus created and fed by an international, enormous in scope and resources R&D effort under the leadership (and the major financial support) of the US Nuclear Regulatory Commission (Office of Nuclear Reactor Regulatory Research) that made possible to meeting the great practical need: assuring and demonstrating the safety of nuclear power reactors. Moreover, it was this juncture in the 1970s and 1980s that afforded the first quantum leap in the scientific development of the subject, and provided the basis for the further developments that were to follow in the intervening 20 years; notably in addressing steam explosions as part of severe accident management in the 1990s (Fletcher and Theofanous 1997) and in spinoffs driven by other practical needs such as the chemical process, oil and gas, and manufacturing industries (catalytic crackers, internal combustion engines, etc).

In these intervening 20 years, at the other extreme of the detailed local level, major strides have been made in the direct solution of the Navier-Stokes equations (DNS), addressing both turbulence and interfacial dynamics. The scope of such simulations is ever enlarging, in pace with ingredients of high-performance computing: machine performance, adaptive mesh platforms, and massively parallelizable schemes. On this basis and with a renewed interest in nuclear power, the “old” systems tools are poised to meet and leverage with these new developments and capabilities toward multi-scale treatments that gain in generality and predictive power as the next generation nuclear power design and safety analysis tools (the CATHARE-NEPTUNE program in France, and the RELAP7 program in the USA). If successful these efforts, both in very early stages of development, are likely to provide the next quantum leap in numerical simulation of multiphase flows. It is in this context that this chapter has been written.

The focus being, as noted above, on the numerical simulation of Flow Regimes, the basic requirements are a 3D representation and a demarcation between regions of space with topologically similar character. For example, in a gas-liquid flow we seek the demarcation between domains of bubbles dispersed in liquid, and domains of drops dispersed in gas. We call these demarcations, as large-scale discontinuities or LSDs (Theofanous and Dinh 2003). In this way

all macroscopic two-phase flows may be seen as interacting assemblages (collective effects of bubbly or droplet flow regions) of disperse flows, and the flow regime identification depends upon the spatial-temporal positioning and multiplicity of the LSDs. As a consequence, coarse-graining or the derivation of effective field (interpenetrating continua) transport equations need only address disperse media, and this focusing is important in eliminating ambiguities inherent with the coarse-graining of internal scales much larger than those of the underlying disperse flows. Moreover, based on typical regime stability requirements the region of interest is over disperse phase volume fractions of less than about 30%. As another key consequence, the numerical solution of the effective field equations must be amenable to grid refinement, so as to capture shocks, contact discontinuities, and the LSDs at arbitrarily sharp focus, and this means, besides the numerical scheme being nondiffusive, that the system of equations be well posed. A further aim in the formulation is to define the phase interaction terms clearly enough as to support the development of closures (a task of renewed potential under DNS) on a physically sound basis. Finally, emerging areas of application require the consideration of supersonic and transonic flows, areas with their own particular demands (Theofanous et al. 2004).

At this basic level of treatment the major attention is given to the dynamics of (inertial or) inviscid interactions between the dispersed and continuous phases (with due account for the so-called pseudo-turbulent fluctuations). These underlie the mathematical character of the system of conservation laws. The incorporation of turbulent stresses and of breakup/coalescence phenomena can be added according to need, for example, in the manner developed by Lahey's and Ishii's teams respectively. Some remarks on the formulation and implications of current systems codes are integrated in ➤ Sect. 6.

Accordingly, in Part I we are particularly interested in a *continuum-mechanical description of mixtures made of many particles dispersed in a carrier fluid*. We will present the two coarse-grained models relevant to the description of dispersed mixtures in ➤ Sect. 2. We will insist on the difficulties inherent to the modeling of the interphase force of the two-fluid model before presenting in ➤ Sect. 3 a special form of the two-fluid model dedicated to the description of dispersions. The non-dissipative version of that model is presented in ➤ Sect. 4 with special emphasis on the role of pseudo-turbulent velocity fluctuations. The dissipative counterpart is presented in ➤ Sect. 5, while some extensions (concerning the role of surface tension in particular) and the main results are recapitulated in ➤ Sect. 6. Emphasis is placed in delivering complete systems of equations that can be taken directly to numerical solution, and as such Part I provides the starting point for Part II. We also aim for clarity on the interfacial momentum transfers — a subject of prolonged, and often confusing debates. Their meaning is not readily open to intuition, while their importance is critical to the well-posedness of the mathematical system that constitutes the effective field model.

2 Basics of Coarse-Graining

2.1 The Two-Fluid Model

The most well-known coarse-grained model is certainly the *two-fluid or two-phase model* (Nigmatulin 1991; Drew and Passman 1998; Ishii and Hibiki 2006) whose exclusive specificity

to disperse systems has been acknowledged only implicitly. In its standard form, the two-fluid model is obtained as a combination of three ingredients:

- The (microscale) conservation equations for mass, momentum, and energy in each of the two phases*
- The function of presence χ_k of phase k in the mixture with $\chi_c + \chi_d = 1$ where the indices c and d stand for the carrier fluid and the dispersed particles respectively*
- A statistical (e.g., ensemble, time, or volume) averaging denoted by $\langle \dots \rangle$*

For example, the microscale momentum balance of phase k is

$$\rho_k^0 \left[\frac{\partial v_k^0}{\partial t} + (v_k^0 \cdot \nabla) v_k^0 \right] = \nabla \cdot \sigma_k^0 + \rho_k^0 g$$

where ρ_k^0 , v_k^0 and σ_k^0 are the microscale mass density, velocity, and stress-tensor. From that microscale conservation equation one deduces the macroscale momentum balances (with no mass exchange between phases, for simplicity here) (Nigmatulin 1991; Drew and Passman 1998; Ishii and Hibiki 2006)

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \langle \chi_c \rho_c^0 v_c' v_c' \rangle = \nabla \cdot \langle \chi_c \sigma_c^0 \rangle - \langle \sigma_c^0 \cdot n_d \delta_I \rangle + \alpha_c \rho_c g, \quad (1)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla \cdot \langle \chi_d \rho_d^0 v_d' v_d' \rangle = \nabla \cdot \langle \chi_d \sigma_d^0 \rangle + \langle \sigma_c^0 \cdot n_d \delta_I \rangle + \alpha_d \rho_d g. \quad (2)$$

Here δ_I is the function of presence of the interfaces between the two phases and n_d is the normal to those interfaces pointing outwards phase d . Moreover, $v_k' = v_k^0 - u_k$ is the velocity fluctuation relative to the mean velocity u_k , $\alpha_k = \langle \chi_k \rangle$ is the volume fraction or probability of presence of phase k , and $d_k/dt = \partial/\partial t + u_k \cdot \nabla$ is a convected time-derivative. These macroscale equations are perfectly symmetric relative to the two phases, i.e., there is no apparent distinction between the continuous and the dispersed phase.

2.2 The Kinetic Theory Model

Concerning the dispersed (particulate) phase there exists a second coarse-grained model, the *kinetic theory model* which is built on the basis of three ingredients:

- The balance equations for the mass momentum and energy of a single particle*
- The microscale number density δ_d of the particles*
- A statistical averaging based on a probability distribution function and denoted by the same symbol $\langle \dots \rangle$ as in the two-fluid approach*

For example, the equation of motion for a single particle is

$$m^0 \frac{dw^0}{dt} = \oint \sigma_c^0 \cdot n_d ds + m^0 g,$$

where m^0 and w^0 are the mass and velocity of a particle. From this equation one deduces the momentum balance of the particulate phase (Buyevich et al. 1978; Lhuillier 1992; Zhang and

Prosperetti 1994; Jackson 1997)

$$nm \left[\frac{\partial w}{\partial t} + (w \cdot \nabla) w \right] + \nabla \cdot [nm \langle w' \otimes w' \rangle] = n \langle \oint \sigma_c^0 \cdot n_d ds \rangle + nmg, \quad (3)$$

where w is the mean translational velocity of the particles, $w' = w^0 - w$ is the fluctuation relative to that mean value, m is the mean mass per particle, and $n = \langle \delta_d \rangle$ is the mean number density of the particles.

This momentum balance is rather similar to that written in the two-phase model except for two remarkable differences: (a) the particle stress which is present in (2) is absent from (3), and (b) the force exerted by the fluid is simply the mean force per particle times the particle number density. The particle stress is not present in the momentum balance but it has not completely disappeared. In fact it is taken into account in a different equation, the *equation for the moment of momentum of the particles* which writes (Lhuillier 1992)

$$\begin{aligned} & \langle \delta_d \frac{d}{dt} \int \rho_d^0 r \otimes u d\tau \rangle - n \langle \int \rho_d^0 u \otimes u d\tau \rangle \\ & = n \langle \oint r \otimes (\sigma_c^0 \cdot n_d) ds \rangle - n \langle \int \sigma_d^0 d\tau \rangle, \end{aligned} \quad (4)$$

where u is the particle-internal motion (a pure rotation for a rigid particle) and r is the vector joining the center of a particle to a point of its surface. The antisymmetric part of the above equation is nothing but the angular momentum balance of the particulate phase. And the symmetric part can be inverted so as to give an explicit expression for the particle stress. When the role of inertia in internal motion can be neglected one recovers Batchelor's expression (Batchelor 1970)

$$\langle \int \sigma_d^0 d\tau \rangle = \frac{1}{2} \langle \oint [r \otimes (\sigma_c^0 \cdot n_d) + (\sigma_c^0 \cdot n_d) \otimes r] ds \rangle. \quad (5)$$

2.3 The Hybrid (Symmetry-Breaking) Model

The main advantage of the kinetic theory model is that it introduces quantities (e.g., the mean force $n \langle \oint \sigma_c^0 \cdot n_d ds \rangle$ acting on the particulate phase), which have a far more intuitive meaning than the corresponding quantity for the two-fluid model (where the interphase force is written as $\langle \sigma_c^0 \cdot n_d \delta_I \rangle$). It would be nice therefore if we could express some two-phase quantities like the mean particle stress or the mean interphase force in terms of quantities pertaining to the kinetic theory approach. This transformation between two-phase and kinetic quantities is in fact well known in electrodynamics of continuous media. One makes such a transformation when writing the mean charge per unit volume as the density of true particle charges minus the divergence of the mean density of particle dipoles, etc. For two-phase flows the corresponding transformations were derived in Buyevich et al. (1978), Lhuillier (1992), Zhang and Prosperetti (1994), and Jackson (1997) with the following general results that apply to any quantity A defined on the interfaces and B defined inside the particles

$$\langle A \delta_I \rangle = n \langle \oint A ds \rangle - \nabla \cdot [n \langle \oint r A ds \rangle] + \dots \quad (6)$$

$$\langle B \chi_d \rangle = n \langle \int B d\tau \rangle - \nabla \cdot [n \langle \int r B d\tau \rangle] + \dots, \quad (7)$$

where the integrals span over the particle surface and the particle volume respectively, and the dots stand for a development in series of higher and higher moments of A and B . When B stands for the small-scale charge density one verifies the well-known result mentioned above and the dots stand for the contributions of particle quadrupoles and higher multipoles. For the modeling of suspensions of particles, A will be the local force exerted by the continuous phase and B will be the local stress inside a particle for which the above transformation rules will be written as

$$\langle \sigma_c^0 \cdot n_d \delta_I \rangle \approx n \langle \oint \sigma_c^0 \cdot n_d ds \rangle - \nabla \cdot [n \langle \oint r \otimes (\sigma_c^0 \cdot n_d) ds \rangle] \quad (8)$$

$$\langle \chi_d \sigma_d^0 \rangle \approx n \langle \int \sigma_d^0 d\tau \rangle \quad (9)$$

One can be surprised that the simplest transformation rule is applied to the particle stress while a more complete one is necessary for the interphase force. The reason is that the particle stress appears with its divergence in the momentum balance. If we limit the interphase force to the first term of the transformation rule we miss a stress term, while if we limit the particle stress to the first term, we only miss higher-order terms comparable to the terms we neglected in the interphase force.

The next step is to introduce the mean pressure p_c of the continuous phase defined as

$$\langle \chi_c \sigma_c^0 \rangle = -\alpha_c p_c I + \langle \chi_c \tau_c^0 \rangle \quad (10)$$

where τ_c^0 is the microscale fluid viscous stress. With the continuous phase pressure and the transformation rules (8) and (9) the two-phase momentum balances, (1) and (2), now appear in a special (hybrid) form

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c + \alpha_c \nabla p_c = -F + \alpha_c \rho_c g \quad (11)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla \cdot \sigma_d + \alpha_d \nabla p_c = F + \alpha_d \rho_d g \quad (12)$$

with the definitions

$$F = n \langle \oint (\sigma_c^0 + p_c I) \cdot n_d ds \rangle \quad (13)$$

$$\sigma_c = \langle \chi_c \rho_c^0 v'_c \otimes v'_c \rangle - \langle \chi_c \tau_c^0 \rangle - n \langle \oint r \otimes (\sigma_c^0 + p_c I) \cdot n_d ds \rangle \quad (14)$$

$$\sigma_d = \langle \chi_d \rho_d^0 v'_d \otimes v'_d \rangle - n \langle \int \rho_d^0 u \otimes u d\tau \rangle + \langle \delta_d \frac{d}{dt} \int \rho_d^0 u \otimes r d\tau \rangle \quad (15)$$

The expression of the dispersed phase stress σ_d was obtained with the help of (4) and (9). The carrier fluid does not play any role in that stress, which vanishes for massless particles. Whenever collisions (or direct inter-particle forces) must be taken into account a collision stress (or an inter-particle stress) is to be added to the right-hand side of (15). In what follows we will use (11) and (12) as the starting point for the two-phase description of suspensions of particles.

It is remarkable that *the dispersed phase pressure nowhere appears in the two momentum equations*, a feature which is specific to dispersed mixtures. We will see however that the pressure difference $p_c - p_d$ is hidden in the stress σ_d and also that it plays a role in the energy equations as

well as in the transport equation for the volume fraction; so that the models we have to present are two-pressure models actually.

The entropy balance equations of the hybrid model are obtained in a similar way. If one neglects the interfacial entropy (linked to surface tension) as well as any entropy production at the interfaces, then the mean specific entropies s_k evolve in time as

$$\alpha_d \rho_d \frac{d_d s_d}{dt} + \nabla \cdot h_d = \Delta_d + \Sigma \quad (16)$$

$$\alpha_c \rho_c \frac{d_c s_c}{dt} + \nabla \cdot h_c = \Delta_c - \Sigma \quad (17)$$

where Δ_k and h_k are the entropy production rate and entropy flux in phase k while Σ is the interphase entropy exchange. These quantities are defined as

$$\Sigma = -n \left\langle \oint \frac{q_c^0}{T_c^0} \cdot n_d ds \right\rangle, \quad (18)$$

$$h_c = \left\langle \chi_c \rho_c^0 s'_c v'_c \right\rangle + \left\langle \chi_c \frac{q_c^0}{T_c^0} \right\rangle + n \left\langle \oint r \left(\frac{q_c^0}{T_c^0} \cdot n_d \right) ds \right\rangle, \quad (19)$$

$$h_d = \left\langle \chi_d \rho_d^0 s'_d v'_d \right\rangle - n \left\langle \int \rho_d^0 s_d^0 u d\tau \right\rangle + \left\langle \delta_d \frac{d}{dt} \int \rho_d^0 s_d^0 r d\tau \right\rangle, \quad (20)$$

where q_c^0/T_c^0 is the microscale entropy flux of the continuous phase. There is an evident similarity with the corresponding definitions for the momentum balances.

3 A General Formulation

The main equations describing a two-phase mixture are the six balance equations for mass, energy, and momentum. The way these equations are obtained is well documented in many textbooks (Nigmatulin 1991; Drew and Passman 1998; Ishii and Hibiki 2006). Here we prefer an entropy balance instead of the energy balance and we will use the hybrid form of the momentum equations as stressed in the previous section. Thus accounting also for phase change, the six main balance equations are written as

$$\frac{\partial}{\partial t} (\alpha_d \rho_d) + \nabla \cdot (\alpha_d \rho_d u_d) = \Gamma \quad (21)$$

$$\frac{\partial}{\partial t} (\alpha_c \rho_c) + \nabla \cdot (\alpha_c \rho_c u_c) = -\Gamma \quad (22)$$

$$\alpha_d \rho_d \frac{d_d s_d}{dt} + \nabla \cdot h_d = \Delta_d + \Sigma + \Gamma (s^* - s_d) \quad (23)$$

$$\alpha_c \rho_c \frac{d_c s_c}{dt} + \nabla \cdot h_c = \Delta_c - \Sigma - \Gamma (s^* - s_c) \quad (24)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla \cdot \sigma_d + \alpha_d \nabla p_c = F + \Gamma (u^* - u_d) + \alpha_d \rho_d g \quad (25)$$

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c + \alpha_c \nabla p_c = -F - \Gamma (u^* - u_c) + \alpha_c \rho_c g. \quad (26)$$

In these equations appear the mass density ρ_k , the entropy density s_k , the volume fraction α_k , and the velocity u_k of phase k ($k = c, d$) together with the mean pressure p_c of the continuous

phase. Besides the entropy production rate $\Delta_k \geq 0$ inside phase k , are defined the intra-phase entropy flux h_k and the stress tensors σ_k together with the exchanges between phases, Γ for the mass exchange, $\Sigma + \Gamma s^*$ for the entropy exchange and $F + \Gamma u^*$ for the momentum exchange. Our aim is to close these equations, i.e., to find by all means (DNS, exact analytical results, phenomenology, etc.) explicit expressions of all averaged quantities (like the stresses σ_c , σ_d and the inter-phase force F but also s^* and u^*) in terms of the basic variables such as the mean velocities and the volume fractions.

To achieve that goal, an important step will be to assume that *the thermodynamic properties of each phase in the mixture are the same as those at work for a pure phase*. This means that the equations of state, which hold when written with local quantities are assumed to hold when written with the mean values of these quantities. In other words, one denies any role to the fluctuations around the mean pressure p_k and the mean temperature T_k inside phase k . But one acknowledges a possible difference between T_c and T_d as well as between p_c and p_d . For example the Gibbs relation of phase k in the mixture will be supposed to be

$$de_k = T_k ds_k - p_k d(1/\rho_k), \quad (27)$$

where e_k is the mean internal energy per unit mass of phase k . For convenience that Gibbs relation is rewritten as

$$\alpha_k \rho_k \frac{d_k e_k}{dt} = T_k \alpha_k \rho_k \frac{d_k s_k}{dt} + \frac{p_k}{\rho_k} \frac{d_k (\alpha_k \rho_k)}{dt} - p_k \frac{d_k \alpha_k}{dt},$$

where $d_k/dt = \partial/\partial t + u_k \cdot \nabla$ is the convected time-derivative of phase k . The evolution equations of the internal energies are then *deduced* from the above evolution equations of entropy and mass per unit volume

$$\begin{aligned} \frac{\partial}{\partial t} (\alpha_d \rho_d e_d) + \nabla \cdot (\alpha_d \rho_d e_d u_d + T_d h_d) &= T_d \Delta_d + T_d \Sigma + h_d \cdot \nabla T_d \\ &+ \Gamma [e_d + T_d (s^* - s_d)] - p_d \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) - \frac{\Gamma}{\rho_d} \right) \end{aligned} \quad (28)$$

$$\begin{aligned} \frac{\partial}{\partial t} (\alpha_c \rho_c e_c) + \nabla \cdot (\alpha_c \rho_c e_c u_c + T_c h_c) &= T_c \Delta_c - T_c \Sigma + h_c \cdot \nabla T_c \\ &- \Gamma [e_c + T_c (s^* - s_c)] - p_c \left(\frac{\partial \alpha_c}{\partial t} + \nabla \cdot (\alpha_c u_c) + \frac{\Gamma}{\rho_c} \right). \end{aligned} \quad (29)$$

Note the first appearance of the dispersed phase pressure and the work of pressure forces in the volume exchange between phases. The balances of the kinetic energies are deduced from the momentum balances

$$\begin{aligned} \frac{\partial}{\partial t} \left(\alpha_d \rho_d \frac{u_d^2}{2} \right) + \nabla \cdot \left(\alpha_d \rho_d \frac{u_d^2}{2} u_d + u_d \cdot \sigma_d + \alpha_d p_c u_d \right) \\ = u_d \cdot F + \sigma_d : \nabla u_d + \Gamma \left(u_d \cdot u^* - \frac{u_d^2}{2} \right) + p_c \nabla \cdot (\alpha_d u_d) + \alpha_d \rho_d u_d \cdot g \end{aligned} \quad (30)$$

$$\begin{aligned} \frac{\partial}{\partial t} \left(\alpha_c \rho_c \frac{u_c^2}{2} \right) + \nabla \cdot \left(\alpha_c \rho_c \frac{u_c^2}{2} u_c + u_c \cdot \sigma_c + \alpha_c p_c u_c \right) \\ = -u_c \cdot F + \sigma_c : \nabla u_c - \Gamma \left(u_c \cdot u^* - \frac{u_c^2}{2} \right) + p_c \nabla \cdot (\alpha_c u_c) + \alpha_c \rho_c u_c \cdot g. \end{aligned} \quad (31)$$

The total phasic energy per unit mass is written as

$$E_k = e_k(\rho_k, s_k) + \frac{u_k^2}{2} + K_k. \quad (32)$$

where K_k is the pseudo-turbulent kinetic energy related to the velocity fluctuations around u_k . It is to be stressed that in a fluid-particles mixture those velocity fluctuations are created by the shear motion of the particles, by the relative motion between the fluid and the particles or by a change in volume or shape of the particles. They disappear as soon as the shear motion, the relative motion, or the particle deformation stops. They are thus quite different from the velocity fluctuations generated by Brownian motion or by turbulence.

After adding the balance of kinetic energy to the balances of internal energy one obtains the following evolution equations for the total energy

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_d \rho_d E_d) + \nabla \cdot (\alpha_d \rho_d E_d u_d + \alpha_d p_c u_d + u_d \cdot \sigma_d + T_d h_d) = & -p_c \frac{\partial \alpha_d}{\partial t} + T_d \Delta_d \\ & + \sigma_d : \nabla u_d + h_d \cdot \nabla T_d + T_d \Sigma + u_d \cdot F + \Gamma(\mu_d + T_d s^* + u_d \cdot u^* - u_d^2/2) \\ & + (p_c - p_d) \left[\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right] + \frac{\partial}{\partial t}(\alpha_d \rho_d K_d) + \nabla \cdot (\alpha_d \rho_d K_d u_d) + \alpha_d \rho_d u_d \cdot g \end{aligned} \quad (33)$$

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c E_c) + \nabla \cdot (\alpha_c \rho_c E_c u_c + \alpha_c p_c u_c + u_c \cdot \sigma_c + T_c h_c) = & -p_c \frac{\partial \alpha_c}{\partial t} + T_c \Delta_c \\ & + \sigma_c : \nabla u_c + h_c \cdot \nabla T_c - T_c \Sigma - u_c \cdot F - \Gamma(\mu_c + T_c s^* + u_c \cdot u^* - u_c^2/2) \\ & + \frac{\partial}{\partial t}(\alpha_c \rho_c K_c) + \nabla \cdot (\alpha_c \rho_c K_c u_c) + \alpha_c \rho_c u_c \cdot g. \end{aligned} \quad (34)$$

In these equations $\mu_k = \epsilon_k + p_k/\rho_k - T_k s_k$ is the chemical potential or Gibbs free-energy per unit mass of phase k . Note the asymmetry concerning the work of the pressure difference $p_d - p_c$, which appears in the equation for the particulate phase only.

We will neglect surface tension and any interfacial energy so that the right-hand sides of the two above equations (apart from the work of external gravity forces) represent the exchange of energy between the two phases and their sum must vanish or must be equal to the divergence of some Galilean-invariant energy flux Q . Hence the *necessary condition* to be fulfilled for the total energy $E = \alpha_d \rho_d E_d + \alpha_c \rho_c E_c$ to be conserved is

$$\begin{aligned} T_d \Delta_d + T_c \Delta_c + (T_d - T_c) \Sigma + (u_d - u_c) \cdot F - (p_d - p_c) \left[\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right] \\ + \Gamma[\mu_d - \mu_c + (T_d - T_c) s^* + (u_c - u^*)^2/2 - (u_d - u^*)^2/2] \\ + \sum_{k=c,d} \left[\frac{\partial}{\partial t}(\alpha_k \rho_k K_k) + \nabla \cdot (\alpha_k \rho_k K_k u_k) + \sigma_k : \nabla u_k + h_k \cdot \nabla T_k \right] + \nabla \cdot Q = 0. \end{aligned} \quad (35)$$

The above equality will play a role of utmost importance for dispersed mixtures and it holds in all cases, whether the carrier fluid is compressible or not, whether the particles are rigid or not. It must be considered as a necessary condition to be satisfied between the (yet unknown) transport equations for α_d , K_d , and K_c and the six main balance equations (21)–(26). Its significance will appear more clearly if we deal first with non-dissipative mixtures and then with dissipative ones.

4 Non-Dissipative Model

When all dissipative phenomena are discarded, condition (35) simplifies to

$$(u_d - u_c) \cdot F^R - (p_d - p_c) \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right) + \sum_{k=c,d} \left[\alpha_k \rho_k \frac{d_k K_k}{dt} + \sigma_k^R : \nabla u_k \right] + \nabla \cdot Q^R = 0. \quad (36)$$

stating the link to be verified between the non-dissipative form of the transport equations for α_d , K_d , and K_c and the non-dissipative parts (with superscript R) of the phasic stresses and the interphase force. We consider the consequences of that equality for cases of increasing complexity.

4.1 Rigid Particles

4.1.1 Rigid Particles, No Velocity Fluctuations

When the particles are rigid and the role of velocity fluctuations is neglected, condition (36) simplifies to $(u_d - u_c) \cdot F^R + \sigma_c^R : \nabla u_c + \sigma_d^R : \nabla u_d + \nabla \cdot Q^R = 0$ and there is apparently no other solution than $F^R = \sigma_c^R = \sigma_d^R = Q^R = 0$. This result holds for compressible as well as incompressible fluid surrounding the (compressible or incompressible) particles. The equations describing that simple non-dissipative case are

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = 0 \quad (37)$$

$$\frac{\partial}{\partial t} (\alpha_c \rho_c) + \nabla \cdot (\alpha_c \rho_c u_c) = 0 \quad (38)$$

$$\frac{d_k s_k}{dt} = 0 \quad (39)$$

$$\alpha_k \rho_k \frac{d_k u_k}{dt} + \alpha_k \nabla p_c = \alpha_k \rho_k g. \quad (40)$$

When the carrier fluid is incompressible (38) is replaced by $\nabla \cdot u = 0$ where $u = \alpha_c u_c + \alpha_d u_d$ is the volume-weighted mean velocity of the mixture and the remaining equations are left unchanged. In all cases (rigid particles in a compressible or incompressible carrier fluid but with negligible velocity fluctuations) the balances of total energy are given by

$$\alpha_k \rho_k \frac{d_k E_k}{dt} + \nabla \cdot (\alpha_k p_c u_k) + p_c \frac{\partial \alpha_k}{\partial t} = \alpha_k \rho_k u_k \cdot g. \quad (41)$$

It is known since long (Gidaspow 1974; Stuhmiller 1977; Jones and Prosperetti 1985) that the above set of non-dissipative equations is not hyperbolic.

4.1.2 Rigid Particles with Added-Mass Velocity Fluctuations

When the carrier fluid is incompressible and its flow is *nonviscous and potential* the two momentum equations (11) and (12) can be written as (see Appendix A):

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c^K + \alpha_c \nabla p_c = -F^K + \alpha_c \rho_c g \quad (42)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla \cdot \sigma_d^K + \alpha_d \nabla p_c = F^K + \alpha_d \rho_d g, \quad (43)$$

with

$$F^K = -\frac{\partial J}{\partial t} - \nabla \cdot (u_d \otimes J) - (J \cdot \nabla) u_c - \alpha_c \rho_c \nabla K_c - J \times (\nabla \times u_c) \quad (44)$$

$$\sigma_c^K = (u_d - u_c) \otimes J \quad (45)$$

where J is the (Kelvin) fluid impulse (defined in (A-8)) and K_c is the fluctuational kinetic energy of the fluid. Note that so far no expression is given for the particle stress σ_d^K . Some general definition exists for this stress tensor (Sangani and Didwania 1993; Bulthuis et al. 1995) but a closed expression in terms of the fluid impulse and other main variables has been difficult to obtain. However, some insight concerning σ_d^K can be provided by condition (36) as developed below.

When particles move relative to the fluid they drag part of the fluid mass with them and they confer the fluid a supplementary kinetic energy. *Neglecting the particles velocity fluctuations* ($K_d = 0$) results in a well-known simplified expression for the fluid pseudo-turbulent (particle-induced) kinetic energy (Geurst 1985; Wallis 1991)

$$K_c = \frac{1}{2} E(\alpha_d) (u_d - u_c)^2, \quad (46)$$

where E is a scalar depending on the particle volume fraction, which behaves like $\alpha_d/2$ for dilute suspensions. There is no real transport equation for K_c but it is possible to deduce from (46)

$$\begin{aligned} \alpha_c \rho_c \frac{d_c K_c}{dt} &= \alpha_c \rho_c \left[E(u_d - u_c) \cdot \frac{d_c}{dt} (u_d - u_c) + \frac{(u_d - u_c)^2}{2} \frac{d_c E}{dt} \right] \\ &= (u_d - u_c) \cdot \left[\frac{\partial J}{\partial t} + \nabla \cdot (u_c \otimes J) \right] - \alpha_c \rho_c \frac{(u_d - u_c)^2}{2} \frac{d_c E}{dt} \end{aligned} \quad (47)$$

where

$$J = \alpha_c \rho_c E(\alpha_d) (u_d - u_c). \quad (48)$$

With F^K and σ_c^K given by the exact results (44) and (45), and noticing that $d_d \alpha_d / dt = -\alpha_d \nabla \cdot u_d$ for rigid particles, the above (pseudo-)transport equation for K_c is finally written as

$$\alpha_c \rho_c \frac{d_c K_c}{dt} = -F^K \cdot (u_d - u_c) - \sigma_c^K : \nabla u_c - \alpha_d P^K \nabla \cdot u_d - \nabla \cdot Q^K. \quad (49)$$

with the pressure P^K and the energy flux Q^K defined as

$$P^K = -\alpha_c \rho_c \frac{\partial K_c}{\partial \alpha_d}, \quad (50)$$

$$Q^K = 2\alpha_c \rho_c K_c (u_d - u_c). \quad (51)$$

When compared to the transport equation for a turbulent kinetic energy, it is worthy to note that (49) exhibits three production terms and one flux (but no dissipation term). Taking (49) into account, relation (36) is satisfied with

$$F^R = F^K, \quad \sigma_c^R = \sigma_c^K, \quad \sigma_d^R = \alpha_d P^K I, \quad Q^R = Q^K. \quad (52)$$

We have thus obtained explicit expressions for the fluid impulse and for the particle stress, which are consistent with assumption (46). It is remarkable that the same scalar $E(\alpha_d)$ appears in the pseudo-turbulent kinetic energy (46) and in the Kelvin impulse (48). This is not true in general as was emphasized by Biesheuvel and Spoolstra (1989) but is a consequence of our neglect of the velocity fluctuations of the particles, as is clear when comparing with the general result (A-13) in Appendix A.

All these results hold for rigid spheres moving in an incompressible carrier fluid. Their extension to a compressible fluid is far from obvious. The velocity disturbances created in the fluid by the particle motion do not propagate instantaneously but with the speed of sound and they are accompanied by mass density disturbances. The simplest approximation is to consider that expression (46) is approximately correct in a compressible carrier fluid. Then it can be shown that identity (49) still holds and consequently, to describe the flow of rigid particles moving in a fluid with added-mass velocity fluctuations described by (46) one needs the following set of six non-dissipative equations

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = 0 \quad (53)$$

$$\frac{\partial}{\partial t} (\alpha_c \rho_c) + \nabla \cdot (\alpha_c \rho_c u_c) = 0 \quad (54)$$

$$\frac{d_d s_d}{dt} = 0, \quad \frac{d_c s_c}{dt} = 0 \quad (55)$$

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c^K + \alpha_c \nabla p_c = -F^K + \alpha_c \rho_c g \quad (56)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla (\alpha_d P^K) + \alpha_d \nabla p_c = F^K + \alpha_d \rho_d g. \quad (57)$$

The corresponding balances of total energies are deduced from (33) and (34) as

$$\alpha_c \rho_c \frac{d_c E_c}{dt} + \nabla \cdot (\alpha_c p_c u_c + u_c \cdot \sigma_c^K + Q^K) + p_c \frac{\partial \alpha_c}{\partial t} = -W^K + \alpha_c \rho_c u_c \cdot g \quad (58)$$

$$\alpha_d \rho_d \frac{d_d E_d}{dt} + \nabla \cdot [\alpha_d (p_c + P^K) u_d] + p_c \frac{\partial \alpha_d}{\partial t} = W^K + \alpha_d \rho_d u_d \cdot g \quad (59)$$

with the inter-phase energy exchange defined as

$$W^K = u_d \cdot F^K + \alpha_d P^K \nabla \cdot u_d. \quad (60)$$

When all terms associated with added-mass kinetic energy vanish we find back the results of [Sect. 4.1.1](#). Note that from (59) the sum $p_c + P^K$ can be considered as the particle pressure.

The mathematical character of the above set of mass and momentum equations has been investigated in Sushchikh and Chang (2009) (summarized in [Appendix B](#)) and, in case of an *incompressible* fluid, it was found that its hyperbolicity requires the function $E(\alpha_d)/\alpha_d$ and its first and second derivatives with respect to α_d (denoted by a prime and a double prime) to satisfy the inequality

$$\left[\alpha_d - \alpha_c \frac{\rho_d}{\rho_c} + (1 - 2\alpha_c) \frac{E}{\alpha_d} + 2\alpha_c \alpha_d \left(\frac{E}{\alpha_d} \right)' \right]^2 \geq \left[\alpha_d + \alpha_c \frac{\rho_d}{\rho_c} + \frac{E}{\alpha_d} \right] \times \left[\alpha_d + \alpha_c \frac{\rho_d}{\rho_c} + \frac{E}{\alpha_d} + 2\alpha_c^2 \alpha_d^2 \left(\frac{E}{\alpha_d} \right)'' \right]. \quad (61)$$

It is interesting to note that this inequality is *independent of the relative velocity* and cannot be satisfied when $E = 0$, that is to say when one neglects the added-mass kinetic energy of the carrier phase.

We looked for expressions of $E(\alpha_d)$ for which the above inequality is satisfied whatever the value of ρ_d/ρ_c . We found that the quadratic expression $E = (\alpha_d/2)(1 + C\alpha_d)$ (hence $(E/\alpha_d)'' = 0$) assures hyperbolicity for any value of the density ratio provided $C \leq -3$. Since $E(\alpha_d)$ must be positive, the choice of a particular value for C defines the range in volume fraction over which hyperbolicity can be assured on physical grounds. For example, with $C = -3$ we have

$$E(\alpha_d) = \frac{\alpha_d}{2}(1 - 3\alpha_d) \quad (62)$$

and hyperbolicity is assured up to $\alpha_d = 1/3$. That special value of C was already pointed out by Geurst (1985) who remarked that it is a sound choice in case of bubbly fluids for which a flow regime transition is expected close to $\alpha_d \approx 0.3$. This choice of C is also supported by theoretical arguments (Wallis 1989, 1991). On the other hand, it must be noted that the physical validity of this second-order expansion, beyond the value of α_d that corresponds to the maximum in E , would appear to require closer examination.

While in bubbly flows the relative velocity is always small and the simplified incompressible analysis is quite adequate, this is not the case for solid particles or drops dispersed in a compressible phase. A complete analysis for this case (Sushchikh and Chang 2009) ([Appendix B](#)) shows that there is a non-hyperbolic corridor around the transonic region that depends weakly on the volume fraction. Clearly, if one demands hyperbolicity for any volume fraction and any Mach number, then new physics must be introduced, involving in particular a description of *particle velocity fluctuations*, either fluid-induced or resulting from collisions. As a consequence (46) would be replaced by a more elaborated expression like

$$K_c = \frac{1}{2}E(\alpha_d, M^*)(u_d - u_c)^2 + F(\alpha_d)K_d. \quad (63)$$

Although the two scalar functions E and F behave as $\alpha_d/2$ in the dilute limit (Zhang and Prosperetti 1994) we cannot take for sure that they are equal for all concentrations. The point is that no closed expression exists for K_d itself or for its transport equation. However if (63) is accepted it is clear that the density $\alpha_d \rho_d + \alpha_c \rho_c F(\alpha_d)$ will play a main role in the transport equation for K_d as well as in the modified form of inequality (61). This is left for later studies.

4.2 Compressible Particles

In dispersed liquid-vapour mixtures the bubbles are highly compressible and the carrier fluid is generally considered as incompressible. To simplify the issue the bubble shape will be assumed to stay spherical and only monodisperse collection of bubbles with a radius $a(x, t)$ will be considered. The bubble radius changes with time and position and a relevant quantity is the convective time-derivative $d_d a/dt$. When mass exchange occurs between the bubbles and the carrier fluid $d_d a/dt$ is different from w_c the mean radial velocity of the fluid at the boundary with the bubbles. In the present section we neglect mass exchanges (a dissipative process) and take $d_d a/dt = w_c$ but to be consistent with the next section dealing with dissipative phenomena, we will consider w_c as the fundamental velocity to describe the non-dissipative radial motion of the bubbles.

The velocity w_c is responsible for a supplementary kinetic energy of the liquid, which adds to the virtual mass kinetic energy. The expression of the pseudo-turbulent kinetic energy K_c becomes

$$K_c = \frac{1}{2} E(\alpha_d) (u_d - u_c)^2 + \frac{1}{2} Q(\alpha_d) w_c^2 \quad (64)$$

where Q is a function of the volume fraction, which behaves like $3\alpha_d$ in the dilute limit. Because of the small mass density of the bubbles it is usual to assume that their kinetic energy of pulsation vanishes and we let $K_d = 0$ in what follows. To describe the motion of the bubbly fluid the momentum equations are completed by two more (non-dissipative) equations (Nigmatulin 1991), the first one being the transport equation for the volume fraction with due account for the bubble expansion rate

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = 3\alpha_d \frac{w_c}{a} \quad (65)$$

and the second one being a generalization to finite volume fractions of the single particle Rayleigh-Lamb equation

$$a \, d_d w_c / dt + (3/2) w_c^2 - (1/4) (u_d - u_c)^2 = (p_d - p_c) / \rho_c .$$

There is also a second quantity that must be properly generalized to finite volume fractions, the total (non-dissipative) stress, which is well known (Nigmatulin 1991) for dilute mixtures

$$\sigma_c^R + \sigma_d^R = \frac{\alpha_d}{2} \rho_c (u_d - u_c) \otimes (u_d - u_c) + \alpha_d (p_d - p_c) I + \alpha_d \rho_c w_c^2 I$$

The two generalizations we are looking for can be deduced from constraint (36).

We insist again that there is no true transport equation for K_c but, because of its dependence on the bubble volume fraction, on the relative velocity and on the bubble expansion rate, one can derive from (64) the identity

$$\begin{aligned} \alpha_c \rho_c \frac{d_c K_c}{dt} \equiv & -(u_d - u_c) \cdot \left(F^K + \frac{R^K}{3\alpha_c} \nabla \alpha_d \right) + \frac{w_c}{a} \left(\frac{R^K}{\alpha_c} + 3\alpha_d P^K - \frac{w_c}{a} M \right) \\ & - \left(\sigma_c^K + \frac{R^K}{3} I \right) : \nabla u_c - \alpha_d \left(P^K + \frac{R^K}{3\alpha_c} \right) \nabla \cdot u_d - \nabla \cdot Q^K . \end{aligned} \quad (66)$$

The Kelvin impulse J is still given by (48) and the quantities F^K , σ_c^K , P^K , and Q^K are still defined by (44), (45), (50), and (51) respectively, but with K_c now given by (64). The only new quantity is R^K which is defined as

$$R^K \equiv \frac{\partial M}{\partial t} + \nabla \cdot (Mu_d), \quad (67)$$

where M is the *scalar* Kelvin impulse of the liquid defined as

$$M = \alpha_c \rho_c Q(\alpha_d) a w_c. \quad (68)$$

The scalar M is playing for the radial motion the same role as the vector J for the relative motion. Taking (65) and (66) into account, relation (36) is satisfied with $Q^R = Q^K$ and

$$F^R = F^K + \frac{R^K}{3\alpha_c} \nabla \alpha_d, \quad \sigma_c^R = \sigma_c^K + \frac{R^K}{3} I, \quad \sigma_d^R = \alpha_d (P^K + \frac{R^K}{3\alpha_c}) I.$$

The generalized Rayleigh-Lamb equation simply appears as

$$\frac{R^K}{\alpha_c} + 3\alpha_d P^K - \frac{w_c}{a} M = 3\alpha_d (p_d - p_c).$$

while the generalized total stress is

$$\sigma_c^R + \sigma_d^R = \sigma_c^K + \alpha_d (p_d - p_c) I + w_c \frac{M}{3a} I.$$

We now gather the above results to obtain the non-dissipative equations for a suspension of spherical bubbles moving in a non-compressible fluid with a pseudo-turbulent kinetic energy given by (64),

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = 3\alpha_d \frac{w_c}{a} \quad (69)$$

$$\frac{\partial \alpha_c}{\partial t} + \nabla \cdot (\alpha_c u_c) = 0 \quad (70)$$

$$\frac{\partial \alpha_d \rho_d}{\partial t} + \nabla \cdot (\alpha_d \rho_d u_d) = 0 \quad (71)$$

$$\frac{d_c s_c}{dt} = 0, \quad \frac{d_d s_d}{dt} = 0 \quad (72)$$

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c^K + \alpha_c \nabla \cdot \left(\frac{R^K}{3\alpha_c} \right) + \alpha_c \nabla p_c = -F^K + \alpha_c \rho_c g \quad (73)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla \cdot (\alpha_d P^K) + \alpha_d \nabla \cdot \left(\frac{R^K}{3\alpha_c} \right) + \alpha_d \nabla p_c = F^K + \alpha_d \rho_d g \quad (74)$$

$$\frac{\partial M}{\partial t} + \nabla \cdot (Mu_d) - \alpha_c \frac{w_c}{a} M = 3\alpha_d \alpha_c (p_d - p_c - P^K). \quad (75)$$

These eight equations reduce to six (see ► Sect. 3.1.2) when the particles are incompressible : this is because (71) is redundant with (69), and (75) reduces to $p_d = p_c + P^K$. Note that this

justifies the statement made in [Sect. 4.1.2](#) that $p_c + P^K$ represents the particle pressure in case of rigid particles.

It is sometimes interesting to have the transport equations for the total energy. The result is an extension of (58) and (59)

$$\begin{aligned} \alpha_c \rho_c \frac{d_c E_c}{dt} + \nabla \cdot \left(\alpha_c p_c u_c + u_c \cdot \sigma_c^K + (\alpha_d u_d + \alpha_c u_c) \frac{R^K}{3\alpha_c} + Q^K \right) \\ + p_c \frac{\partial \alpha_c}{\partial t} = -W^K + \alpha_c \rho_c u_c \cdot g \end{aligned} \quad (76)$$

$$\alpha_d \rho_d \frac{d_d E_d}{dt} + \nabla \cdot [\alpha_d (p_c + P^K) u_d] + p_c \frac{\partial \alpha_d}{\partial t} = W^K + \alpha_d \rho_d u_d \cdot g. \quad (77)$$

with the inter-phase energy exchange given by

$$W^K = u_d \cdot \left[F^K - \alpha_d \nabla \left(\frac{R^K}{3\alpha_c} \right) \right] + \alpha_d P^K \nabla \cdot u_d - 3\alpha_d (p_d - p_c) \frac{w_c}{a}. \quad (78)$$

The transport equation (65) for the particle volume fraction holds whether the fluid around the bubbles is compressible or not. In case of a compressible fluid the Rayleigh-Lamb equation (75) is modified (Keller and Miksis 1980). We showed with (68) that the Rayleigh-Lamb equation is intimately related to the fluid fluctuational kinetic energy and a possible way to represent the fluid compressibility is to start from a modified expression like

$$K_c = \frac{1}{2} E(\alpha_d, M^*) (u_d - u_c)^2 + \frac{1}{2} Q \left(\alpha_d, \frac{w_c}{c_c} \right) w_c^2 \quad (79)$$

where c_c is the isentropic sound speed of the carrier fluid. Deducing $\alpha_c \rho_c d_c K_c / dt$ and following the same route as above one can derive the new Rayleigh-Lamb equation in a compressible fluid. The main advantage of the method is that a lot of complex results can be deduced from rather simple expressions for the pseudo-turbulent kinetic energies. It is clear however that we supposed the particles to be spheres of variable radius. This is tenable in so far as the bubbles are not distorted by the mean flow or by the presence of neighbor particles. This simplistic description of the particle internal motion is certainly not the most general one but is the one that prevails at not too high particle volume fraction and for not too large bubbles.

5 Dissipative Model

This section will consider dissipative processes in dispersed mixtures. For condition (35) to be satisfied the first issue is to propose complete transport equations for α_d , K_d , and K_c . These transport equations are very different depending upon whether the particles are compressible or not and we will consider the two cases separately.

5.1 Noncompressible Particles: Solid Grains or Drops

5.1.1 The Dissipation Rate

Because the issue of particle velocity fluctuations has not yet been solved we assume for simplicity that $K_d = 0$ while K_c is given by the added-mass expression (46). Since we now deal with dissipative phenomena we must take mass exchanges (phase transitions) into account and the transport equation for the fluid pseudo-turbulent energy writes (compare with the former expression (49))

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c K_c) + \nabla \cdot (\alpha_c \rho_c K_c u_c) = & -F^K \cdot (u_d - u_c) - \sigma_c^K : \nabla u_c \\ & - \alpha_d P^K \nabla \cdot u_d - \nabla \cdot Q^K + P^K \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right) + \Gamma K_c . \end{aligned} \quad (80)$$

As seen in ► Sect. 4.1.2, the pressure difference for rigid particles results from a Bernoulli effect expressed as

$$p_d - p_c = P^K . \quad (81)$$

Hence the transport equation for the volume fraction disappears from the condition for energy conservation (35), which is transformed into an expression for the total dissipation rate

$$\begin{aligned} T_d \Delta_d + T_c \Delta_c = & -(T_d - T_c) \Sigma - (u_d - u_c) \cdot (F - F^K) - h_c \cdot \nabla T_c - h_d \cdot \nabla T_d \\ & - \Gamma [\mu_d - \mu_c + (T_d - T_c) s^* + (u_c - u^*)^2/2 - (u_d - u^*)^2/2 + K_c] \\ & - (\sigma_c - \sigma_c^K) : \nabla u_c - (\sigma_d - \alpha_d P^K I) : \nabla u_d - \nabla \cdot (Q - Q^K) . \end{aligned}$$

This expression is not yet fully satisfactory: For a dispersed mixture a dissipation rate involving ∇u_d or ∇T_d holds when the particles are in permanent contact or display frequent collisions. At variance the particulate stress originating from the viscosity of the carrier fluid and the entropy flux originating from its heat conductivity must be described differently. These fluid-induced stresses and heat fluxes will be represented in what follows by τ and h and one expects them to give rise to a dissipation rate $\tau \cdot \nabla u + h \cdot \nabla T$ (Batchelor 1970; Prosperetti et al. 1998; Lhuillier 2003) where

$$u = \alpha_d u_d + \alpha_c u_c , \quad T = \alpha_d T_d + \alpha_c T_c , \quad (82)$$

are the mean velocity and mean temperature of the whole suspension. The simplest way to obtain the desired result is to adopt the definitions

$$\begin{aligned} F &= F^K + f - \alpha_d \nabla \cdot \tau , \\ \sigma_c &= \sigma_c^K + \tau , \\ \sigma_d &= \alpha_d P^K I , \\ Q &= Q^K + (T - T_c) h + (u - u_c) \cdot \tau , \\ h_d &= 0 , \\ h_c &= h , \\ \Sigma &= H - \alpha_d \nabla \cdot h . \end{aligned}$$

With these definitions the initial equations (21)–(26) are transformed into

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = \frac{\Gamma}{\rho_d} \quad (83)$$

$$\frac{\partial}{\partial t} (\alpha_c \rho_c) + \nabla \cdot (\alpha_c \rho_c u_c) = -\Gamma \quad (84)$$

$$\alpha_d \rho_d \frac{d_d s_d}{dt} + \alpha_d \nabla \cdot h = \Delta_d + H + \Gamma (s^* - s_d) \quad (85)$$

$$\alpha_c \rho_c \frac{d_c s_c}{dt} + \alpha_c \nabla \cdot h = \Delta_c - H - \Gamma (s^* - s_c) \quad (86)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla (\alpha_d p^K) + \alpha_d \nabla \cdot \tau + \alpha_d \nabla p_c = F^K + f + \Gamma (u^* - u_d) + \alpha_d \rho_d g \quad (87)$$

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c^K + \alpha_c \nabla \cdot \tau + \alpha_c \nabla p_c = -F^K - f - \Gamma (u^* - u_c) + \alpha_c \rho_c g. \quad (88)$$

Note that, at variance with most two-fluid models, there is a single viscous stress and a single heat flux and that $\nabla \cdot \tau$ and $\nabla \cdot h$ are shared in proportion to the volume fractions. With the above definitions the total dissipation rate becomes

$$\begin{aligned} T_d \Delta_d + T_c \Delta_c = & -(T_d - T_c)H - (u_d - u_c) \cdot f - h \cdot \nabla T - \tau \cdot \nabla u \\ & - \Gamma [\mu_d - \mu_c + (T_d - T_c)s^* + (u_c - u^*)^2/2 - (u_d - u^*)^2/2 + K_c]. \end{aligned} \quad (89)$$

Expression (89) plays a very important role for dissipative phenomena, similar to the role played by (36) for non-dissipative ones. The quantity $T_d \Delta_d + T_c \Delta_c$ is slightly different from the total entropy production rate $\Delta_d + \Delta_c$ but it represents a closely related quantity, the total energy dissipation rate in the mixture. And instead of the usual thermodynamic inequalities $\Delta_d \geq 0$ and $\Delta_c \geq 0$ we will rely on the related inequality $T_d \Delta_d + T_c \Delta_c \geq 0$. Hence the right-hand side of (89) must be positive in all circumstances.

5.1.2 The Constitutive Laws

According to (89) there are five different sources of dissipation corresponding to the the heat, momentum, and mass exchanges at interfaces together with the heat and momentum transport through the bulk of the mixture. The thermodynamic forces associated with these five kinds of dissipation have the intuitively expected form except for the one linked to mass exchange, which is associated with a disequilibrium involving u^* and s^* . Since the mass exchange (phase transition rate) is expected to be driven by thermodynamic quantities mainly, with a limited influence of the relative velocity, the best choice for u^* is apparently

$$u^* = \frac{u_c + u_d}{2}. \quad (90)$$

That special value for u^* was adopted by several authors (Baer and Nunziato 1986; Young 1995) but a different one ($u^* = u_d$) was preferred by Marble (1969) who supposed that no thrust force could act on the particles due to mass exchange. At variance (90) implies that the same thrust force acts on the two phases of the mixture. In other words, with choice (90) there is no “rocket

effect” due to mass exchange. Concerning the specific entropy s^* Marble (1969) suggested (for liquid droplets surrounded by their vapor) to choose

$$s^* = s_c \quad (91)$$

because all the latent heat of the phase transitions are provided by (or given to) the droplets. If we adopt Marble’s choice, the driving force for mass exchange between a noncompressible particle and its vapor is

$$\mu_c - \mu_d + s_c(T_c - T_d) \simeq (s_c - s_d)(T_{sat}(p_c) - T_d),$$

with $T_{sat}(p_c)$ the saturation temperature at the continuous phase pressure. The dissipation rate is now rewritten in the final form

$$\begin{aligned} T_d \Delta_d + T_c \Delta_c &= (T_c - T_d)H + (u_c - u_d) \cdot f - \tau \cdot \nabla u - h \cdot \nabla T \\ &+ \Gamma[(s_c - s_d)(T_{sat}(p_c) - T_d) - K_c] \geq 0. \end{aligned} \quad (92)$$

Concerning the exchanges at interfaces a positive dissipation is guaranteed with the constitutive laws

$$H = \kappa(T_c - T_d), \quad (93)$$

$$f = \zeta(u_c - u_d), \quad (94)$$

$$\Gamma = \gamma[(s_c - s_d)(T_{sat}(p_c) - T_d) - K_c] \quad (95)$$

where ζ , κ , and γ are three positive transport coefficients. The above expressions are the simplest ones with no coupling at all between the dissipative exchanges. Concerning the viscous and heat transport through the bulk of the mixture the constitutive laws are in their simplest form

$$\sigma = -\eta \nabla u \quad (96)$$

$$h = -\lambda \nabla T \quad (97)$$

where η and λ are the effective viscosity and effective heat conductivity of the mixture and are positive transport coefficients that depend on the particle volume fraction. More complicated non-Newtonian constitutive relations are possibly obeyed by σ and non-Fourier ones by h . Whatever the chosen expressions they must satisfy the thermodynamic constraint expressed by inequality (92).

Once the expression of the total dissipation rate $T_d \Delta_d + T_c \Delta_c$ has been obtained, one must decide the way it is shared between its phasic components $T_d \Delta_d$ and $T_c \Delta_c$. Baer and Nunziato (1986) proposed that the dissipation from compaction is apportioned to the dispersed phase and the dissipation from drag to the continuous phase (nothing is said concerning the thermal dissipation and mass exchange dissipation). Then it was shown in Bdzil et al. (1999) that many other choices are possible, involving up to four sharing coefficients, one for each type of interfacial dissipation. Marble (1969) proposed to give the whole dissipation to the continuous phase and this is obviously the simplest solution that we here adopt because the internal velocity field and internal temperature field inside a particle is not likely to give rise to a heat source that can compete with the heat exchanged through interfaces. We thus assume

$$\Delta_d = 0. \quad (98)$$

We acknowledge that this is a crude assumption but the use of sharing coefficients would be a source of complication for the model without any guaranty of improvement.

5.2 Compressible Particles: Bubbles

5.2.1 The Dissipation Rate

We neglect the pseudo-turbulent kinetic energy of the particles ($K_d = 0$) and assume that the pseudo-turbulent kinetic energy of the carrier fluid is given by (64) from which is deduced the pseudo-transport equation

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c K_c) + \nabla \cdot (\alpha_c \rho_c K_c u_c) = & -(u_d - u_c) \cdot F^K - \sigma_c^K : \nabla u_c - \alpha_d P^K \nabla \cdot u_d \\ & + \frac{w_c}{a} \left(R^K - \frac{\dot{a}}{a} M \right) + P^K \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right) - \nabla \cdot Q^K + \Gamma K_c, \end{aligned} \quad (99)$$

where $\dot{a} = d_d a / dt$ and all other quantities are defined in  Sect. 4.2. Concerning the transport of the particle volume fraction we now take mass exchange into account and (65) is transformed into its dissipative counterpart

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = 3\alpha_d \frac{w_c}{a} + \frac{\Gamma}{\rho_c}. \quad (100)$$

a result obtained from the boundary condition for radial velocities at interfaces

$$\frac{3\alpha_d}{a} w_c + \frac{\Gamma}{\rho_c} = \frac{3\alpha_d}{a} w_d + \frac{\Gamma}{\rho_d}. \quad (101)$$

With the two above transport equations, condition (35) for energy conservation now turns into

$$\begin{aligned} T_d \Delta_d + T_c \Delta_c + (T_d - T_c) \Sigma + (u_d - u_c) \cdot (F - F^K - \Delta P \nabla \alpha_d) + \Gamma [\mu_d - \mu_c + (T_d - T_c) s^* \\ - (p_d - p_c - P^K) / \rho_c + (u_c - u^*)^2 / 2 - (u_d - u^*)^2 / 2 + K_c] \\ + (\sigma_c - \sigma_c^K - \alpha_c \Delta P I) : \nabla u_c + (\sigma_d - \alpha_d P^K I - \alpha_d \Delta P I) : \nabla u_d \\ + (w_c / a) (R^K - 3\alpha_c \Delta P) + h_c \cdot \nabla T_c + h_d \cdot \nabla T_d + \nabla \cdot (Q - Q^K) = 0 \end{aligned} \quad (102)$$

where the generalized pressure difference ΔP is defined by

$$\Delta P = \alpha_d (p_d - p_c - P^K) + \frac{\dot{a}}{a} \frac{M}{3}. \quad (103)$$

We now follow the same strategy as for incompressible particles and introduce the definitions

$$\begin{aligned}
 F &= F^K + \Delta P \nabla \alpha_d + f - \alpha_d \nabla \cdot \tau, \\
 \sigma_c &= \sigma_c^K + \alpha_c \Delta P I + \tau, \\
 \sigma_d &= \alpha_d P^K I + \alpha_d \Delta P I, \\
 Q &= Q^K + (T - T_c)h + (u - u_c) \cdot \tau, \\
 h_d &= 0, \\
 h_c &= h, \\
 \Sigma &= H - \alpha_d \nabla \cdot h.
 \end{aligned}$$

To these definitions we add the generalized Rayleigh-Lamb equation written as

$$R^K + 12\alpha_d \alpha_c \eta_c \frac{w_c}{a} = 3\alpha_c \Delta P, \quad (104)$$

where η_c is the viscosity of the carrier fluid. Hence the final set of equations can be written as

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = 3\alpha_d \frac{w_c}{a} + \frac{\Gamma}{\rho_c} \quad (105)$$

$$\frac{\partial \alpha_d \rho_d}{\partial t} + \nabla \cdot (\alpha_d \rho_d u_d) = \Gamma \quad (106)$$

$$\frac{\partial \alpha_c \rho_c}{\partial t} + \nabla \cdot (\alpha_c \rho_c u_c) = -\Gamma \quad (107)$$

$$\alpha_d \rho_d \frac{d_d s_d}{dt} + \alpha_d \nabla \cdot h = \Delta_d + H + \Gamma(s^* - s_d) \quad (108)$$

$$\alpha_c \rho_c \frac{d_c s_c}{dt} + \alpha_c \nabla \cdot h = \Delta_c - H - \Gamma(s^* - s_c) \quad (109)$$

$$\begin{aligned}
 \alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c^K + \alpha_c \nabla \cdot \tau + \alpha_c \nabla (p_c + \Delta P) \\
 = -F^K - f - \Gamma(u^* - u_c) + \alpha_c \rho_c g
 \end{aligned} \quad (110)$$

$$\begin{aligned}
 \alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla (\alpha_d P^K) + \alpha_d \nabla \cdot \tau + \alpha_d \nabla (p_c + \Delta P) \\
 = F^K + f + \Gamma(u^* - u_d) + \alpha_d \rho_d g
 \end{aligned} \quad (111)$$

$$\frac{R^K}{3\alpha_c} + 4\alpha_d \eta_c \frac{w_c}{a} = \Delta P, \quad (112)$$

while the total dissipation rate becomes

$$\begin{aligned}
 T_d \Delta_d + T_c \Delta_c = -(T_d - T_c)H - (u_d - u_c) \cdot f - h \cdot \nabla T - \tau \cdot \nabla u + 12\alpha_d \alpha_c \eta_c \left(\frac{w_c}{a} \right)^2 \\
 - \Gamma[\mu_d - \mu_c + (T_d - T_c)s^* - (p_d - p_c - P^K)/\rho_c + K_c],
 \end{aligned} \quad (113)$$

where the special value of u^* given in (90) was used. The main difference with the case of incompressible particles is the existence of a new source of dissipation linked to the radial motion and a new term involving the pressure difference in the thermodynamic force driving the mass exchange.

5.2.2 The Constitutive Laws

Most of the constitutive laws (those for H , f , h , τ , and u^*), as well as the assumption $\Delta_d = 0$, are unchanged compared to the case of incompressible particles. There are however two remarkable differences, the value of s^* and the constitutive law for Γ . The gas bubbles can hardly provide or receive the latent heat associated with mass exchange while the liquid around them is a good candidate for that role. Hence it is likely that

$$s^* = s_d \quad (114)$$

so that the entropy balance of the bubbles (85) is independent of the mass exchange. The driving force for mass exchange between a bubble and the surrounding liquid is then

$$\mu_c - \mu_d + s_d(T_c - T_d) - \frac{1}{\rho_c}(p_c - p_d) \simeq (s_d - s_c)(T_c - T_{sat}(p_d)),$$

and the mass exchange at interfaces is given by

$$\Gamma = \gamma[(s_d - s_c)(T_c - T_{sat}(p_d)) - K_c - P^K/\rho_c] \quad (115)$$

The role of the two terms related to velocity fluctuations is presumably negligible.

5.3 Final Form of the Model

The above analysis of two special cases (incompressible particles and highly compressible ones) suggests that $\Delta_d = 0$ and u^* is given by (90). As a consequence the initial equations (21)-(26) are conveniently replaced for *any dispersed mixture* by

$$\frac{\partial}{\partial t}(\alpha_d \rho_d) + \nabla \cdot (\alpha_d \rho_d u_d) = \Gamma \quad (116)$$

$$\frac{\partial}{\partial t}(\alpha_c \rho_c) + \nabla \cdot (\alpha_c \rho_c u_c) = -\Gamma \quad (117)$$

$$\alpha_d \rho_d \frac{d_d s_d}{dt} + \alpha_d \nabla \cdot h = H + \Gamma(s^* - s_d) \quad (118)$$

$$\alpha_c \rho_c \frac{d_c s_c}{dt} + \alpha_c \nabla \cdot h = \Delta_c - H - \Gamma(s^* - s_c) \quad (119)$$

$$\begin{aligned} \alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla \cdot \sigma_d^R + \alpha_d \nabla \cdot \sigma + \alpha_d \nabla p_c \\ = F^R + f + \Gamma(u_c - u_d)/2 + \alpha_d \rho_d g \end{aligned} \quad (120)$$

$$\begin{aligned} \alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla \cdot \sigma_c^R + \alpha_c \nabla \cdot \sigma + \alpha_c \nabla p_c \\ = -F^R - f + \Gamma(u_c - u_d)/2 + \alpha_c \rho_c g, \end{aligned} \quad (121)$$

The resulting balance equations for internal energy are

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_d \rho_d e_d) + \nabla \cdot (\alpha_d \rho_d e_d u_d) &= T_d(H - \alpha_d \nabla \cdot h) + \Gamma[e_d + T_d(s^* - s_d)] \\ &\quad - p_d \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) - \frac{\Gamma}{\rho_d} \right) \end{aligned} \quad (122)$$

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c e_c) + \nabla \cdot (\alpha_c \rho_c e_c u_c + Th) &= T_c \Delta_c + (T_d - T_c)H + h \cdot \nabla T \\ &\quad - T_d(H - \alpha_d \nabla \cdot h) - \Gamma[e_c + T_c(s^* - s_c)] - p_c \left(\frac{\partial \alpha_c}{\partial t} + \nabla \cdot (\alpha_c u_c) + \frac{\Gamma}{\rho_c} \right). \end{aligned} \quad (123)$$

while the conservation of total energy requires

$$\begin{aligned} T_c \Delta_c &= -(T_d - T_c)H - (u_d - u_c) \cdot (f + F^R) - h \cdot \nabla T - \sigma : \nabla u \\ &\quad - \Gamma[\mu_d - \mu_c + (T_d - T_c)s^*] + (p_d - p_c)[\partial \alpha_d / \partial t + \nabla \cdot (\alpha_d u_d)] \\ &\quad - \sum_{k=c,d} \left[\frac{\partial}{\partial t}(\alpha_k \rho_k K_k) + \nabla \cdot (\alpha_k \rho_k K_k u_k) + \sigma_k^R : \nabla u_k \right] - \nabla \cdot (Q^R). \end{aligned}$$

Hence transport equations are needed for α_d , K_d , and K_c in order to deduce the final form of the entropy production rate Δ_c . In principle, if one of the two phases is incompressible the transport equation for the volume fraction is no longer independent since it stems from the mass balance. The transport equations for the pseudo-turbulent kinetic energies will provide explicit expressions for the non-dissipative stresses σ_c^R , σ_d^R and the non-dissipative force F^R . Conversely, these three quantities are likely to disappear in case one denies any role to the velocity fluctuations. The entropy flux h is fully dissipative while σ is the sum of a viscous stress (noted τ in [Sect. 5.1](#) and [Sect. 5.2](#)) and a second part representing all phenomena (depicted by ΔP in [Sect. 5.2](#)), which play a role in the pressure difference.

When collisions between particles are relevant they are taken into account with a stress tensor σ^{coll} and an entropy flux h^{coll} . A force $\nabla \cdot \sigma^{coll}$ is to be added on the left-hand side of the momentum balance (120) of the particulate phase and similarly $\nabla \cdot h^{coll}$ is to be added to the left-hand side of (118). Any physically admissible closure for σ^{coll} and h^{coll} must verify the positivity of the energy production rate $-(\sigma^{coll} : \nabla u_d + h^{coll} \cdot \nabla T_d)$.

6 Summary of Key Results

6.1 Hybrid Approach for Dispersed Mixtures

The two-phase model (built on the characteristic function of presence χ_k) is capable, formally at least, to describe any kind of mixture. In case of dispersed mixtures with particles suspended in a carrier fluid its main drawback is the lack of reference to what happens to one particle and this has important implications on the closure problem. This is an old issue and an early example was given by Batchelor (1970) who expressed (see (9) and (5)) the dispersed stress $\langle \chi_d \sigma_d^0 \rangle$ of the two-phase model in terms of the so-called particle stresslet, which is the first moment of the fluid force exerted on the particle surface $n < \oint r \otimes (\sigma_c^0 \cdot n_d) ds >$.

The presence of the small-scale number density δ_d is typical of a kinetic theory approach of the particulate phase and it happens that we know the general rules that allow to transform two-phase quantities into quantities pertaining to the kinetic theory approach. With these transformation rules elaborated in Buyevich and Schelchkova (1978), Lhuillier (1992), Zhang and Prosperetti (1994), and Jackson (1997) not only we can generalize Batchelor's result for the dispersed phase stress (see results (9) and (4)), but we also obtain a relation between the inter-phase forces of the two models (see result (8)). The later relation is remarkable and shows that the inter-phase force of the two-phase model is not only the mean force per particle times the particle number density, but that it also involves the particle stresslet. A first consequence is that the particle stresslet appears in the momentum balance of the fluid phase exclusively. A second consequence is that the two-phase momentum balances are to be written as (25) and (26) for a dispersed mixture. In these two equations nowhere appears the pressure of the dispersed phase, but only the continuous phase pressure involved in some Archimedes force apportioned to the volume fractions.

This does not mean that the dispersed phase pressure can be discarded. The models that were described above are clearly "two-pressure" models, which show that in case of compressible particles the dispersed phase pressure is involved in the compression work appearing in the energy balance equations, not to mention its influence in the transport equation for the volume fraction. Conversely, whenever the energy equations decouple from the other equations (a widely spread but debatable assumption), the only pressure that remains is that of the continuous phase and a one-pressure model is enough to describe the flow. Note also that we refrained introducing a "mean interfacial pressure" p_I as is done currently in many two-phase models and the reason is clear : we decided at the outset to work with the two mean pressures only and, to be consistent, we had no possibility for introducing a third pressure. Some forces however were deduced that look like $p_I \nabla \alpha_d$ or $(p_I - p_c) \nabla \alpha_d$. But such forces never occur alone and are part of a more general force such as $\nabla(\alpha_d P^K)$ in the case of added-mass phenomena. Focusing the efforts on a $p_I \nabla \alpha_d$ or $(p_I - p_c) \nabla \alpha_d$ type of force is thus too restrictive, it is part of the truth only.

Both in this philosophy of approaching inviscid interaction and in the final results we find agreement with Wallis (1991) and Geurst (1985). Having been derived independently and with completely different methodologies (let alone nomenclatures) these three formulations may appear completely different, however, we have verified that they are completely equivalent. In the case of Geurst, one must understand that what he calls the hydrodynamic pressure is nothing but the mean pressure $p = \alpha_c p_c + \alpha_d p_d$. In the case of Wallis, one must understand that he adopts a slightly different definition of the interphase force, which amounts to $F^K + \nabla \cdot \sigma_c^K$ and consequently the kinetic stress $(u_d - u_c) \otimes J$ is assigned to the particulate phase instead of the fluid phase.

6.2 Supplementary Equations

The standard two-fluid model is made of six equations, representing the balances of mass, momentum, and energy for each of the two phases. Do we need more equations? The answer depends on a delicate balance between precision and efficiency. Using more equations means needing more closure relations and facing more difficulties with the numerical simulations. New equations are needed for mainly two reasons: A better description of the

physics and a better description of the geometry of the interfaces (and sometimes a mixture of the two).

6.2.1 Pseudo-Turbulent Kinetic Energies

Flow-induced velocity fluctuations are at the origin of a rather formidable problem sometimes coined as “pseudo-turbulence.” Much like what happens for the true turbulence one is led to introduce new equations giving the evolution in time (and coupling with the mean flow) of quantities like the pseudo-turbulent kinetic energies or the pseudo-turbulent kinetic stresses. Such supplementary equations are of common use for the description of collision-induced velocity fluctuations of particles moving in a gas but they are still in their infancy for particles moving in a liquid of almost matching density. In the above presentation of the two-phase model we have not taken collisions into account (the divergence of a collision stress must, in some cases, be added to the right-hand side of (15)) and we were not able to propose a general form for the time evolution of the pseudo-turbulent kinetic energy or kinetic stresses. But we have insisted on two particular kinds of flow-induced velocity fluctuations, those associated with the relative fluid-particle motion and those associated with the pulsating motion of particles. These two special cases are relatively simple in so far as the related pseudo-turbulent kinetic energies are given by analytical expressions like (46) or (64) and instead of new equations we have just derived the pseudo-equations (49) and (66). But these pseudo-equations give a flavor of what the two extra equations for K_d and K_c may look like, while the constraint (35) details the way these new equations should be coupled to the six two-phase equations.

6.2.2 Volume Fraction Transport

The volume fraction is a parameter that is of crucial significance to the two-phase model. Is it necessary to write an extra equation for one of the two volume fractions? Obviously not when the particles are assumed to be incompressible because the transport equation for volume is then a mere consequence of the transport equation for mass, and this is independent of the compressibility of the continuous phase. For compressible particles new physics must be introduced, and the answer is readily obtained provided one makes simplifying assumptions concerning the particle deformation. The simplest answer is obtained with (100) after supposing that all the particles are monodispersed spheres. This introduces an extra geometric variable, the radial velocity w_c at interfaces, which is coupled to the mean flow by the Rayleigh-Lamb equation (112). Hence this is not one but two coupled extra equations that are needed in case of compressible particles. The only exception is the case of a *slow radius change* because the inertia of the liquid in the radial motion can be neglected, the Rayleigh-Lamb equation then reduces to $4\eta_c(w_c/a) = p_d - p_c$ and the transport equation for the volume fraction appears as

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) = \frac{3\alpha_d}{4\eta_c} (p_d - p_c) + \frac{\Gamma}{\rho_c}. \quad (124)$$

We thus need an eight-equation model or a seven-equation model depending whether the inertia of the continuous phase is important or not for the radial motion of the particles. Moreover,

when phase changes occur at sufficiently slow rates to assure thermodynamic equilibrium, then (124) is replaced by the fluid equation of state, thus reverting back to the six-equation model.

A seven-equation model was proposed by Baer and Nunziato (1986) but with a transport equation for the volume fraction that markedly differs from (124) since the left-hand side of (124) is replaced by a convective time-derivative $\partial\alpha_d/\partial t + V_I \cdot \nabla\alpha_d$ where V_I is sometimes called the mean interfacial velocity. That convective time-derivative was taken for granted in many subsequent works (Bdzil et al. 1999; Kapila et al. 2001; Abgrall and Saurel 2003). However, while a transport equation with a convective time-derivative is correct for separated flows averaged over a cross section (Ransom 1984/1988), its use cannot be extended to the dispersed mixtures we have considered here and for which (124), or more generally (100), is the correct answer.

6.2.3 Interfacial Energy Transport

Besides the volume fraction the density of interfacial area a_I defined as

$$a_I = \langle \delta_I \rangle \quad (125)$$

is also an important parameter for the inter-phase exchanges. The volume fraction and the interfacial area density are connected to each other via the mean particle radius $3\alpha_d/a_I$. For a monodisperse suspension of spheres one then obtains the transport equation

$$\frac{\partial a_I}{\partial t} + \nabla \cdot (a_I u_d) = \frac{2a_I}{3\alpha_d} \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right). \quad (126)$$

The interfacial energy of the mixture is γa_I where γ is the surface tension. Requiring the total energy $\alpha_d \rho_d E_d + \alpha_c \rho_c E_c + \gamma a_I$ to be conserved leads to a dissipation rate similar to (113) but with p_d replaced everywhere by $p_d - 2\gamma a_I/3\alpha_d$ with the consequence that $p_d = p_c + 2\gamma a_I/3\alpha_d$ at equilibrium. The above transport equation is very simple but it requires the particles to keep a spherical shape and it neglects the coalescence, break-up, and nucleation phenomena. When these phenomena occur, new terms appear in the right-hand side and an example is given below concerning the particle deformation. Concerning coalescence and break-up the main issue is to select the relevant physical phenomena (turbulence of the carrier phase, relative motion of the two phases, etc.) and the way the polydispersity of the particles modifies the intensity of the processes.

6.2.4 Particle Deformation and Dynamics of Interfaces

When the particles are deformable and depart from a spherical shape, another quantity (a tensor in general) will be needed to depict the deformations of the interfaces and their coupling to the ambient flow. Introducing a tensor as a new variable brings a lot of difficulties but it provides a way to explain part (and only part) of the lateral drift experienced by deformable particles (drops or bubbles) in a pipe flow. Usually deformable particles move toward places where they are deformed less. In a pipe flow the region of smallest deformation is the pipe axis where the

shear vanishes. Since the particle deformability depends on their size (and more generally on the capillary number) the larger particles will drift and accumulate close to the pipe axis while the smaller ones will be less sensitive to that drift and will have a more homogeneous distribution over the pipe cross section.

Other effects due to the particle deformability are known to exist such as non-Newtonian behavior of the mixture with difference of normal stresses and shear-dependent viscosity. Doi and Ohta (1991) proposed to describe the interfacial microstructure with two quantities, the interfacial area density and the anisotropy tensor $q_{ij} = \langle (n_i n_j - \delta_{ij}/3) \delta_I \rangle$, where n is the unit vector normal to the interfaces, and they derived two coupled evolution equations for q_{ij} and a_I . Their model, however was restricted to a very special flow with $\alpha_d \approx 0.5$ and equal viscosities of the two phases. Many subsequent works tried to go beyond that special case and are presented in Tucker and Moldenaers (2002).

It is possible to use the above-defined anisotropy tensor for a dispersed mixture with $\alpha_d < 0.5$. But it is much more convenient to use $C_{ij} = q_{ij}/a_I$ as the anisotropy tensor with

$$C_{ij} = \frac{\langle (n_i n_j - \frac{\delta_{ij}}{3}) \delta_I \rangle}{\langle \delta_I \rangle}. \quad (127)$$

As an example we give below the two coupled equations for an emulsion of two immiscible and incompressible phases where the interfaces are those of (slightly) deformed spheres and viscous effects are dominant. With $p = \eta_d/\eta_c$ the ratio of the droplet viscosity to the carrier viscosity, α_d the droplet volume fraction, and $\sigma + \sigma_I$ the emulsion viscoelastic stress (see Appendix C for the definition (C4) of the interfacial stress σ_I) one obtains (Lhuillier 2003)

$$\frac{\partial a_I}{\partial t} + \nabla \cdot (a_I u_d) = -a_I \mathbf{C} : \left(\frac{F}{H} \mathbf{D} + \frac{1}{2H} \frac{\gamma a_I}{\alpha_d \eta_c} \mathbf{C} \right) \quad (128)$$

$$\frac{\partial \mathbf{C}}{\partial t} + (u_d \cdot \nabla) \mathbf{C} + \mathbf{C} \cdot \Omega - \Omega \cdot \mathbf{C} = -\frac{8}{15} \left[\frac{F}{H} \mathbf{D} + \left(\frac{1}{2H} + \frac{3}{19p+16} \right) \frac{\gamma a_I}{\alpha_d \eta_c} \mathbf{C} \right] \quad (129)$$

$$\sigma + \sigma_I = -2\eta_c \left[1 + \alpha_d(p-1) \frac{F}{H} \right] \mathbf{D} + \frac{F}{H} \gamma a_I \mathbf{C} \quad (130)$$

where D and Ω are the strain rate and rotation rate of the suspension mean velocity $u = \alpha_d u_d + \alpha_c u_c$. Moreover, $H(p, \alpha_d) = p - 1 + F(\alpha_d)$ while $F(\alpha_d)$ is related to the effective viscosity of a suspension of hard spheres, with $F(\alpha_d) = 5/2(1 - \alpha_d)$ as one of the simplest possible expressions (Palierne 1990). In the two above transport equations for C_{ij} and a_I one clearly distinguishes the two main phenomena: the shear-induced deformation and the retraction due to surface tension. But the breakup and coalescence phenomena are not represented and must be taken into account by extra terms. The above three equations were written for incompressible particles. The compressibility of particles has a role in the transport equation for a_I only, the right-hand side of which is then the sum of the two right-hand sides of (126) and (128).

6.3 Hyperbolicity

Ill-posedness has been a major issue in regards to the formulation of the two-phase model since the very early efforts on behalf of nuclear reactor safety in the early 1970s (Gidaspow 1974),

and all along the way to the most recent renditions (Drew and Passman 1998; Prosperetti and Satrape 1990; RELAP5/MOD3.3 Code Manual 2001). Inviscid interactions between the phases were anticipated as the cause, and a number of empirical or ad hoc additions have been made as constitutive descriptions mainly under the names of “added mass” e.g., (Park et al. 1998) and “interfacial pressure” e.g., (Stuhmiller 1977), but the overall subject seems to still lack in clarity and definiteness. On the other hand, the unified treatments of these interactions in Wallis (1991) and independently in Geurst (1985) seemed to have gone unnoticed. These results are recovered completely independently in the present development, and so is a generalization of the requirement for hyperbolicity found in Geurst (1985) for incompressible flows (low Mach number limit in the present work) equation (62). This result is completely adequate for disperse systems as its applicability, which coincides with the natural range of disperse phase volume fractions being under about 30%. At still higher concentrations particle collisions have to be taken into account, as indeed the role of particle fluctuation adding to the kinetic energy as explained by (63). On the other hand, for highly compressible flows the function E in (46) must be redefined to include the effect of flow Mach number, and this further (and hopefully final) development of the subject will be an important task for the future. For the time being, in practical terms we have found that the present formulation is sufficient to obtain robust numerical solutions at all flow speeds (Part II).

The approach of Baer and Nunziato (1986) must be mentioned in this context. These authors proposed, for dense particulate systems, one of the rare models to be hyperbolic. Why are we skeptical concerning the potentialities of that model for dispersed mixtures? We pointed out above a strong discrepancy concerning the transport equation for the volume fraction. Another important discrepancy concerns the two momentum balances which, in the BN model, appear as

$$\alpha_c \rho_c \frac{d_c u_c}{dt} + \nabla(\alpha_c p_c) = -f - \Gamma(u^* - u_c) + \alpha_c \rho_c g \quad (131)$$

$$\alpha_d \rho_d \frac{d_d u_d}{dt} + \nabla(\alpha_d p_d) = f + \Gamma(u^* - u_d) + \alpha_d \rho_d g \quad (132)$$

These equations are different from (26) and (25). The gradient of the dispersed phase pressure is assumed to drive the motion of the dispersed phase while we claimed that the gradient of p_c is the only driving force for both the carrier fluid and the dispersed phase. It is true that the special way the momentum and volume fraction equations were written was enough to ensure hyperbolicity. But the paradox is that hyperbolicity is obtained with a set of equations that is definitely not suitable for particulate systems.

6.4 Nuclear Reactor (Design) Systems Codes

Here we specifically refer to the RELAP5 developed in the USA during the 1970s and the French code CATHARE that followed; they are the main representatives of the genre. They are based on the premise that flow and transport of heat/mass can be captured generally for all flow regimes by one and the same set of effective field equations (a system of six equations plus the equations of state of the fluids involved). These equations were written in 1D, as (channel) cross-sectional averages, and augmented by volume sources and/or sinks that represent the wall transfers. The later are determined by a logic that reflects the estimated flow pattern on the basis of vapor and liquid flow rates and other pertinent quantities. The RELAP5 code is well documented in a

comprehensive set of volumes that is openly available (RELAP5/MOD3.3 Code Manual 2001). For CATHARE the main reference is a journal paper by Bestion (1990). The comments below are based on these sources, and we focus on the momentum equations as they are the critical link to hyperbolicity, and thus to the numerical performance of these computer codes.

For RELAP5, the afore-mentioned equations are formally the same as the 1D version of (42) and (43), except for the following: (a) The phases are assumed to be at the same pressure, so in the gradient term instead of p_c write p ; (b) both phasic stresses are absent; (c) from the added-mass force only the component $\partial(u_d - u_c)/\partial t$ is retained; and (d) there are source terms to express wall transfers as noted above. For CATHARE, the spatial derivatives of the added mass term are retained and the Stuhmiller (1977) treatment of interfacial pressure is added to “render the system hyperbolic.” It is known that with an appropriate selection of the coefficient in this expression the system becomes hyperbolic for incompressible flows, but there is no consideration of the effect of Mach number. For sensitive problems the results can depend on the value of this coefficient. The RELAP5 system of equations is ill-posed and solutions are obtained by controlling the growth of oscillations. In particular, damping is affected by means of added artificial viscosity terms, and by keeping the size of the (numerical grid) nodes sufficiently large. An interesting part of the RELAP5 numerical stability analysis (RELAP5/MOD3.3 Code Manual 2001) is that the drag terms stabilize the solution down to sufficiently small wavenumbers as to render solutions for nuclear reactor scale systems practicable.

Much of the utility of these codes rests upon the dominance of phase-change effects present in applications, which these codes were intended for to begin with (nuclear reactor loss of coolant accidents). In a way this, along with conservation, provides an attractor strong enough to be a basis for tuning by means of experiments.

Acknowledgments

This work was supported by the Joint Science and Technology Office, Defense Threat Reduction Agency (JSTO/DTRA), and the National Ground Intelligence Center (NGIC) of the US Army (Dr. Richard Babarsky). Dr. S. Sushchikh and Dr. C.-H. Chang (CRSS / UCSB) participated with many helpful discussions and derivations concerning the hyperbolicity issue and comparison to other formulations. Lively discussions with (and useful comments from) Dr. C. Morel (CEA Grenoble) and Professor R. Saurel (IUSTI Marseille) are gratefully acknowledged.

Appendix A: Rigid Spheres in a Nonviscous Fluid

Our aim is to give a brief derivation of the fluid momentum balance (42) with definitions (44) and (45). We consider many rigid spheres dispersed in a nonviscous and noncompressible fluid. The momentum balances of the two phases are expressed by the general equations (11) and (12) but definitions (13)–(15) simplify to

$$F = \langle \delta_d \oint (p_c - p) n_d ds \rangle \quad (\text{A-1})$$

$$\sigma_c = \rho_c \langle \chi_c v'_c \otimes v'_c \rangle - \langle \delta_d \oint (p_c - p) r \otimes n_d ds \rangle \quad (\text{A-2})$$

$$\sigma_d = \rho_d \langle \chi_d v'_d \otimes v'_d \rangle \quad (\text{A-3})$$

where p is the microscale fluid pressure and p_c is its mean value. Note that we neglected the kinetic contribution to σ_d because the internal motion u is reduced to a rotation in case of rigid particles and the angular velocity is a constant when the rigid particles have a spherical shape. Hence the inter-phase force is linked to the pressure fluctuations on the surfaces of the particles while the phasic stresses depend on both the pressure and velocity fluctuations. To make some progress we must be able to calculate the various terms on the right-hand sides of definitions (A-1) to (A-3). This can be done if we further suppose that the nonviscous fluid has a microscale velocity v deriving from the potential ϕ . In that case the microscale equations of motion are

$$v = \nabla \phi, \quad \nabla^2 \phi = 0, \quad (\text{A-4})$$

$$\frac{\partial \phi}{\partial t} + \frac{v^2}{2} + \frac{p}{\rho_c} - g \cdot x = 0. \quad (\text{A-5})$$

The fluid velocity is split into a mean value u_c and a fluctuation v'

$$v = u_c + v', \quad \langle \chi_c v \rangle = \alpha_c u_c, \quad \langle \chi_c v' \rangle = 0. \quad (\text{A-6})$$

With Wallis (1991) we split the velocity potential into an averaged value Φ and a fluctuation ϕ' defined by

$$\phi = \Phi + \phi', \quad \langle \chi_c \phi \rangle = \alpha_c \Phi, \quad \langle \chi_c \phi' \rangle = 0. \quad (\text{A-7})$$

A quantity that will prove of utmost importance is the mean fluid impulse J defined by

$$J = \rho_c \langle \chi_c \nabla \phi' \rangle = -\rho_c \langle \phi' n_d \delta_I \rangle. \quad (\text{A-8})$$

J is a Galilean-invariant momentum, which plays a role in both the mean velocity and the velocity fluctuations

$$v' = \nabla \phi' - \frac{J}{\alpha_c \rho_c}, \quad u_c = \nabla \Phi + \frac{J}{\alpha_c \rho_c}, \quad \nabla \times \left(u_c - \frac{J}{\alpha_c \rho_c} \right) = 0. \quad (\text{A-9})$$

It is now rather easy to deduce the momentum balance of the fluid phase. The microscale Bernoulli equation (A-5) is multiplied by the fluid characteristic function χ_c and one performs the statistical average noted by brackets $\langle \dots \rangle$. The result is the averaged Bernoulli equation

$$\alpha_c \frac{\partial \Phi}{\partial t} + \langle \chi_c \frac{\partial \phi'}{\partial t} \rangle + \langle \chi_c \frac{v^2}{2} \rangle + \frac{\alpha_c p_c}{\rho_c} - \alpha_c g \cdot x = 0. \quad (\text{A-10})$$

Taking the gradient of that equation and eliminating $\nabla \Phi$ with the help of (A-9) one obtains

$$\frac{\partial}{\partial t} \left(u_c - \frac{J}{\alpha_c \rho_c} \right) + \frac{1}{2} \nabla \left(u_c - \frac{J}{\alpha_c \rho_c} \right)^2 - \nabla K^* + \frac{\nabla p_c}{\rho_c} = g, \quad (\text{A-11})$$

where K^* is a specific kinetic energy related to the fluid impulse J and to the pseudo-turbulent fluid kinetic energy $K_c = \langle \chi_c v'^2 \rangle / 2\alpha_c$ by

$$2\alpha_c K^* = 2\alpha_c K_c + \alpha_c \left(\frac{J}{\alpha_c \rho_c} \right)^2 - 2 \nabla \cdot \langle \chi_c \phi' \nabla \phi' \rangle. \quad (\text{A-12})$$

Moreover, the pseudo-turbulent kinetic energy of the fluid is itself related to the Kelvin impulse by

$$2\alpha_c K_c = (u_d - u_c) \cdot \frac{J}{\rho_c} - \langle \phi' (v - u_d) \cdot n_d \delta_I \rangle + \nabla \cdot \langle \chi_c \phi' \nabla \phi' \rangle. \quad (\text{A-13})$$

Equation (A-11) can be transformed into a momentum balance similar to (11) with

$$-F - \nabla \cdot \sigma_c = \frac{\partial J}{\partial t} + \nabla \cdot (u_c \otimes J) + (J \cdot \nabla)(u_c - \frac{J}{\alpha_c \rho_c}) + \alpha_c \rho_c \nabla K^* \quad (\text{A-14})$$

The main conclusion at this point is that *the dynamics of the fluid phase depends on two quantities only*, the mean fluid impulse J and the kinetic energy K^* . We can simplify the above result (A-14) if we assume the last term of (A-12) to be negligible. Then, the non-dissipative force acting on the fluid phase becomes

$$-F - \nabla \cdot \sigma_c = \frac{\partial J}{\partial t} + \nabla \cdot (u_c \otimes J) + (J \cdot \nabla)u_c + \alpha_c \rho_c \nabla K_c + J \times (\nabla \times u_c) \quad (\text{A-15})$$

where, according to (A-9), $\nabla \times u_c$ in the last term can be replaced by $\nabla \times (J/\alpha_c \rho_c)$ at will. It is clear that the above equation of motion is equivalent to (42) with definitions (44) and (45). Note however that our splitting into a force F^K and a stress σ_c^K is somehow arbitrary in so far as only the sum $F^K + \nabla \cdot \sigma_c^K$ can be deduced unambiguously from expression (A-15).

Appendix B: Hyperbolicity Aspects of the Effective Field Model with S. Sushchikh and C.-H. Chang

Here our aim is to study the mathematical character of the system (53)–(57), and as is common practice we do so in one space dimension. While the procedures are standard, the derivations are rather laborious and results for the fully compressible case (high Mach numbers) are presented here for the first time. These results are of essential use in Part II.

The system of equations is:

$$\frac{\partial}{\partial t}(\alpha_c \rho_c) + \frac{\partial}{\partial x}(\alpha_c \rho_c u_c) = 0 \quad (\text{B-1a})$$

$$\frac{\partial}{\partial t}(\alpha_d \rho_d) + \frac{\partial}{\partial x}(\alpha_d \rho_d u_d) = 0 \quad (\text{B-1b})$$

$$\frac{\partial}{\partial t}(\alpha_c \rho_c u_c) + \frac{\partial}{\partial x}[\alpha_c \rho_c u_c^2 + \alpha_c \rho_c E (u_d - u_c)^2] + \alpha_c \frac{\partial p_c}{\partial x} = -F^K \quad (\text{B-1c})$$

$$\frac{\partial}{\partial t}(\alpha_d \rho_d u_d) + \frac{\partial}{\partial x}[\alpha_d \rho_d u_d^2 + \alpha_d P^K] + \alpha_d \frac{\partial p_c}{\partial x} = F^K \quad (\text{B-1d})$$

With

$$\begin{aligned}
 F^K &= -\frac{\partial J}{\partial t} - \frac{\partial}{\partial x}(u_d J) - J \frac{\partial u_c}{\partial x} - \alpha_c \rho_c \frac{\partial K_c}{\partial x} \\
 J &= \alpha_c \rho_c E(\alpha_d)(u_d - u_c) \\
 K_c &= \frac{1}{2} E(\alpha_d)(u_d - u_c)^2 \\
 P^K &= -\alpha_c \rho_c \frac{\partial K_c}{\partial \alpha_d} \\
 &= p_d - p_c
 \end{aligned}$$

Equation of state information is introduced by defining the isentropic speeds of sound for each field:

$$a_c^2 = \frac{\partial p_c}{\partial \rho_c} \quad \text{and} \quad a_d^2 = \frac{\partial p_d}{\partial \rho_d}$$

We will cast this system in characteristic form and will determine the eigenvalues, first analytically, in the incompressible approximation, and then numerically for any Mach number flow.

In the standard wave equation form the above system becomes:

$$\mathbf{A} \frac{\partial Q}{\partial t} + \mathbf{B} \frac{\partial Q}{\partial x} = 0 \quad (\text{B-2})$$

where $Q = (\alpha_d, u_d, u_c, p_c)^T$ is the vector of primitive variables, and matrixes $\mathbf{A}$ and $\mathbf{B}$ are:

$$\mathbf{A} = \begin{pmatrix} A_{11} & A_{12} & A_{13} & A_{14} \\ -\rho_c & 0 & 0 & \alpha_c / a_c^2 \\ \alpha_c \rho_c E'(u_d - u_c) & \alpha_d \rho_d + \alpha_c \rho_c E & -\alpha_c \rho_c E & 0 \\ -\alpha_c \rho_c E'(u_d - u_c) & -\alpha_c \rho_c E & \alpha_c \rho_c + \alpha_c \rho_c E & 0 \end{pmatrix} \quad (\text{B-3})$$

$$\mathbf{B} = \begin{pmatrix} u_d A_{11} & \alpha_d \rho_d + u_d A_{12} & u_d A_{13} & u_d A_{14} \\ -\rho_c u_c & 0 & \alpha_c \rho_c & \alpha_c u_c / a_c^2 \\ B_{31} & B_{32} & B_{33} & B_{34} \\ B_{41} & -\alpha_c \rho_c u_d E & \alpha_c \rho_c (1 + E) u_c & \alpha_c \end{pmatrix} \quad (\text{B-4})$$

with:

$$\begin{aligned}
 A_{11} &= \rho_d - \frac{\alpha_d \rho_c (\alpha_c E'' - E')(u_c - u_d)^2}{2a_d^2} & A_{12} &= -A_{13} = -\alpha_c \alpha_d \rho_c E'(u_d - u_c) / a_d^2 \\
 A_{14} &= \frac{\alpha_d}{a_d^2} - \frac{\alpha_c \alpha_d E'(u_c - u_d)^2}{2a_d^2 a_c^2}
 \end{aligned}$$

And:

$$\begin{aligned}
 B_{31} &= \frac{1}{2}\rho_c(u_d - u_c)^2(\alpha_d E' - 2E - \alpha_c \alpha_d E'') + \alpha_c \rho_c E' u_d(u_d - u_c) \\
 B_{41} &= -\frac{1}{2}\alpha_c \rho_c E'(u_d - u_c)(u_d + u_c) \\
 B_{32} &= \alpha_d \rho_d u_d - \alpha_c \alpha_d \rho_c E'(u_d - u_c) + 2\alpha_c \rho_c E(u_d - u_c) + \alpha_c \rho_c u_d E \\
 B_{33} &= -\alpha_c \rho_c E u_c + \alpha_c \rho_c(u_d - u_c)(\alpha_d E' - 2E) \\
 B_{34} &= \alpha_d + \frac{1}{2}\alpha_c(2E - \alpha_d E') \frac{(u_d - u_c)^2}{a_c^2}
 \end{aligned}$$

The eigenvalues of (B-2) can be calculated by solving: $|\mathbf{B} - \lambda \mathbf{A}| = 0$ or letting $\mathbf{D} = \mathbf{B} - \lambda \mathbf{A}$, we have to solve:

$$|\mathbf{D}| = \begin{vmatrix} (u_d - \lambda)A_{11} & \alpha_d \rho_d + (u_d - \lambda)A_{12} & (u_d - \lambda)A_{13} & (u_d - \lambda)A_{14} \\ -\rho_c(u_c - \lambda) & 0 & \alpha_c \rho_c & \alpha_c(u_c - \lambda)/a_c^2 \\ D_{31} & D_{32} & D_{33} & D_{34} \\ D_{41} & -\rho_c E(u_d - \lambda) & \rho_c(1 + E)(u_c - \lambda) & 1 \end{vmatrix} = 0 \quad (\text{B-5})$$

Where:

$$\begin{aligned}
 D_{31} &= \alpha_c \rho_c E'(u_d - u_c)(u_d - \lambda) + \rho_c/2(\alpha_d E' - 2E - \alpha_c \alpha_d E'')(u_d - u_c)^2 \\
 D_{32} &= (\alpha_d \rho_d + \alpha_c \rho_c E)(u_d - \lambda) + \alpha_c \rho_c(2E - \alpha_d E')(u_d - u_c) \\
 D_{33} &= \alpha_c \rho_c E(u_c - \lambda) - \alpha_c \rho_c(2E - \alpha_d E')(u_d - u_c) \\
 D_{34} &= \alpha_d + \frac{\alpha_c(2E - \alpha_d E')}{2a_c^2}(u_c - u_d)^2 \\
 D_{41} &= \rho_c E'(u_d - u_c)(\lambda - \frac{1}{2}(u_d + u_c))
 \end{aligned}$$

Equation (B-5) will lead to a fourth-order polynomial equation (quartic equation) whose roots (eigenvalues) will be examined analytically; first in the low Mach number approximation (B-1), and then numerically for the general case (B-2). We seek conditions for which all four roots are real for this is a necessary and sufficient requirement for our system to be hyperbolic.

B.1 Low Mach Number Approximation

Under the conditions (Hancox et al. 1980):

$$\begin{aligned}
 (u_c - \lambda) &\ll a_k \\
 (u_d - \lambda) &\ll a_k \quad k = c, d \\
 (u_d - u_c) &\ll a_k
 \end{aligned}$$

equation (B-5) simplifies to:

$$\begin{vmatrix} (u_d - \lambda) & \alpha_d & 0 & 0 \\ -(u_c - \lambda) & 0 & \alpha_c & 0 \\ D_{31} & D_{32} & D_{33} & \alpha_d \\ D_{41} & -\rho_c E(u_d - \lambda) & \rho_c(1 + E)(u_c - \lambda) & 1 \end{vmatrix} = 0 \quad (\text{B-6})$$

which under the transformation $X = \lambda - \frac{u_d + u_c}{2}$, can be written as:

$$K_2 X^2 + K_1 X + K_0 = 0 \quad (\text{B-7})$$

with

$$\begin{aligned} K_2 &= \alpha_d (\alpha_c \rho_d + \alpha_d \rho_c) + \rho_c E \\ K_1 &= (u_d - u_c) [\alpha_d (\alpha_d \rho_c - \alpha_c \rho_d) + (1 - 4\alpha_c) \rho_c E + 2\alpha_c \alpha_d \rho_c E'] \\ K_0 &= \frac{(u_d - u_c)^2}{4} [\alpha_d (\alpha_d \rho_c + \alpha_c \rho_d) + \rho_c E + 2\alpha_c^2 \rho_c (2E - 2\alpha_d E' + \alpha_d^2 E'')] \end{aligned} \quad (\text{B-8})$$

Thus, as a condition for real roots we must have $K_1^2 \geq 4K_2 K_0$ and accordingly:

$$\begin{aligned} &\left(\alpha_d - \alpha_c \bar{\rho} + (1 - 4\alpha_c) \frac{E}{\alpha_d} + 2\alpha_c E' \right)^2 \geq \\ &\left(\alpha_d + \alpha_c \bar{\rho} + \frac{E}{\alpha_d} \right) \cdot \left(\alpha_d + \alpha_c \bar{\rho} + \frac{E}{\alpha_d} + 4\alpha_c^2 \left[\frac{E}{\alpha_d} - E' + \frac{\alpha_d}{2} E'' \right] \right) \end{aligned} \quad (\text{B-9})$$

where the density ratio is $\bar{\rho} = \rho_d / \rho_c$.

For example, if we write $E(\alpha_d) = C_1 \alpha_d + C_2 \alpha_d^2$, the hyperbolicity condition becomes:

$$4\alpha_c \alpha_d (\bar{\rho} + C_1)(1 + C_1 + C_2) \leq 0 \quad (\text{B-10})$$

Coefficients C_1 and C_2 also have to satisfy that $E(\alpha_d) > 0$. The choice made by Geurst (1985), $C_1 = 1/2$ and $C_2 = -3/2$, satisfies these conditions, although (B-10) provides considerably more latitude. We also know that the $C_1 = 1/2$ provides the correct asymptotic limit as $\alpha_d \rightarrow 0$, although remarkably, the second term is still needed for hyperbolicity. While there is some theoretical basis for the $C = C_2/C_1 \sim -3$ value, the function $E(\alpha_d)$ needs better understanding and elaboration for dense systems.

The eigenvalues, actually the “eigenspeeds” of our system, are the roots of (B-7):

$$\lambda_{1,2} = u_d - \left(\frac{\alpha_d (1 + C_1 + C_2) \mp \sqrt{-\alpha_c \alpha_d (\bar{\rho} + C_1)(1 + C_1 + C_2)}}{\alpha_d + \alpha_c \bar{\rho} + C_1 + C_2 \alpha_d} \right) (u_d - u_c) \quad (\text{B-11})$$

Now for bubbly ($\bar{\rho} \ll 1$) and droplet ($\bar{\rho} \gg 1$) flows (B-11) simplifies to:

$$\text{droplet: } \lambda_{1,2} = u_d \pm \frac{\sqrt{\frac{\alpha_d}{\alpha_c}} \sqrt{-(1 + C_1 + C_2)} (u_d - u_c)}{\sqrt{\bar{\rho}}} \approx u_d \quad (\text{B-11a})$$

$$\text{bubbly: } \lambda_{1,2} = u_d \pm \sqrt{-\alpha_d \alpha_c (1 + C_1 + C_2) / C_1} (u_d - u_c) \quad (\text{B-11b})$$

and we note that the “eigenspeeds” behave quite differently in the two cases. On the other hand, and for either case, with the Geurst choice we have exactly $\lambda_{1,2} = u_d$.

For bubbly flows the above analysis is quite sufficient since the attainment of high relative velocities in practice is severely limited by interfacial breakup (which tends to homogenize the flow). For droplet or particle flows on the other hand, high relative velocities are not only realizable, they are of the greatest interest in practice. For such flows the low Mach number analysis is a point of departure for the more general treatment provided in the following.

B.2 A General Treatment

Allowing for compressibility of the continuous phase (droplet, or particle flows in gas) the matrix of interest becomes:

$$\mathbf{D} = \begin{pmatrix} u_d - \lambda & \alpha_d & 0 & 0 \\ -\rho_c(u_c - \lambda) & 0 & \alpha_c \rho_c & \alpha_c(u_c - \lambda)/a_c^2 \\ D_{31} & D_{32} & D_{33} & D_{34} \\ D_{41} & -\rho_c E(u_d - \lambda) & \rho_c(1 + E)(u_c - \lambda) & 1 \end{pmatrix} \quad (\text{B-12})$$

The appropriate nondimensional treatment involves two characteristic Mach numbers: one based on the average velocity of the mixture, M^* , and the other on the relative velocity of the phases, $\hat{M}$, where:

$$M^* = \frac{(u_d + u_c)}{2a_c} \quad (\text{B-13})$$

$$\hat{M} = \frac{(u_d - u_c)}{2a_c} \quad (\text{B-14})$$

Accordingly, the Mach numbers for each of the “eigenspeeds” are $\lambda_i^* = \lambda_i/a_c$, and with $Y = \lambda^* - M^*$ equation (B-5) yields:

$$(Y + \hat{M})^2(Y - \hat{M})^2 + K_2^*(Y - \hat{M})^2(Y + \hat{M}) + K_3^*(Y - \hat{M})(Y + \hat{M})^2 + K_4^*(Y - \hat{M})^2 + K_5^*(Y + \hat{M})^2 + K_6^*(Y - \hat{M})(Y + \hat{M}) + K_7^*(Y - \hat{M}) + K_8^*(Y + \hat{M}) + K_9^* = 0 \quad (\text{B-15})$$

where:

$$K_2^* = \frac{2\hat{M}(1 - \alpha_d)E(\alpha_d E' - 2E)}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)}; \quad K_3^* = -\frac{2\hat{M}(1 - \alpha_d)(\alpha_d E'(2 + E) - 2E(1 + E))}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)};$$

$$K_4^* = \frac{4\hat{M}^2(1 - \alpha_d)E(\alpha_d E' - E)}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)} - \frac{(1 - \alpha_d)E + \alpha_d \bar{\rho}}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)};$$

$$K_5^* = \frac{2\hat{M}^2\alpha_d^2(1 - \alpha_d)E''(1 + E)}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)} - \frac{\alpha_d^2(1 + E)}{(1 - \alpha_d)(E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E))};$$

$$K_6^* = -\frac{4\hat{M}^2\alpha_d(1 - \alpha_d)E'(\alpha_d E' - E)}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)} - \frac{2\alpha_d E}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)};$$

$$K_7^* = -\frac{4\hat{M}(E - \alpha_d E') + 2\alpha_d^2 \hat{M} E' + 4\alpha_d^2 (E')^2 \hat{M}^3}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)};$$

$$K_8^* = \frac{2\alpha_d^2 \hat{M} E'(1 + 2(1 - \alpha_d)\hat{M}^2 E')}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)}; \quad K_9^* = -\frac{2\alpha_d^2(1 - \alpha_d)\hat{M}^2(E'' - 2(E')^2\hat{M}^2)}{E(1 - \alpha_d) + \alpha_d \bar{\rho}(1 + E)}.$$

As shown by Bronshtein et al. (2007), the roots of this quartic can be analyzed in terms of a resolvent cubic equation. The key steps are summarized in the following.

Rendered in the form:

$$Y^4 + p_3 Y^3 + p_2 Y^2 + p_1 Y + p_0 = 0 \quad (\text{B-16})$$

the original quartic is transformed to:

$$Y^4 + aY^2 + bY + c = 0, \quad (\text{B-17})$$

according to $a = -\frac{3}{8}p_3^2 + p_2$, $b = \frac{1}{8}p_3^3 - \frac{p_2p_3}{2} + p_1$ and $c = -\frac{3}{256}p_3^4 + \frac{p_2p_3^2}{16} - \frac{p_1p_3}{4} + p_0$. Then corresponding to (B-17) resolvent cubic equation is:

$$T^3 + rT^2 + sT + t = 0 \quad (\text{B-18})$$

with $r = 2a$, $s = a^2 - 4c$ and $t = b^2$. The quartic equation has four real roots if and only if corresponding resolvent has three real positive roots.

The roots of cubic equation are examined in terms of $Z = T + r/3$ so that (B-18) becomes:

$$Z^3 + pZ + q = 0 \quad (\text{B-19})$$

with $p = (3s - r^2)/3$; $q = 2r^3/27 - rs/3 + t$.

and for three real positive roots we must have:

$$D = \left(\frac{p}{3}\right)^3 + \left(\frac{q}{2}\right)^2 \leq 0 \quad \text{and} \quad (\text{B-20a})$$

$$T_k = Z_k - (r/3) > 0. \quad (\text{B-20b})$$

Here Z_k are obtained by

$$\begin{aligned} Z_1 &= 2\sqrt[3]{\omega} \cos\left(\frac{\phi}{3}\right); \\ Z_2 &= 2\sqrt[3]{\omega} \cos\left(\frac{\phi}{3} + \frac{2\pi}{3}\right); \\ Z_3 &= 2\sqrt[3]{\omega} \cos\left(\frac{\phi}{3} + \frac{4\pi}{3}\right). \end{aligned}$$

where $\omega = \sqrt{\frac{-p^3}{27}}$ and $\phi = \cos^{-1}\left(\frac{-q}{2\omega}\right)$.

Once functional form of $E(\alpha_d)$ is provided, the hyperbolicity boundaries can be found by numerically scanning the domain of parameter space $\hat{M}, \alpha_d, \bar{\rho}$. For the particular example considered here, we remain with the form taken for the low Mach number analysis above, with $C_1 = 1/2$ so that

$$E(\alpha_d) = \frac{1}{2}\alpha_d(1 + C\alpha_d) \quad (\text{B-21})$$

where C is now introduced as an additional parameter. As long as $\bar{\rho} \gg 1$ the results are insensitive to the actual value (10^3 is the value for which results are shown here). Also, as expected, and in contradistinction to bubbly flows, the hyperbolicity boundaries are insensitive to the presence of the added mass term, although the term is included for the results shown here.

Representative results of this type of analysis are summarized in  Fig. B1, and we can see that they correctly recover the low Mach number analysis presented above. Notable is also the increase of accessible Mach numbers within the hyperbolic domain (so that $E(\alpha_d)$ remains positive) with decreasing disperse phase volume fraction.

Perhaps more important is the finding that *in all cases* the non-hyperbolic corridor is characterized by exceedingly small but positive values (typically of order 10^{-12}) of the discriminant

Figure B1

Representative sample of hyperbicity maps of our effective field model employed for droplet (or particles in gas) flows. The Mach number(M) here is without the factor of 1/2 found in (B-14)

D , which can be thought of as a symptom of “mild” non-hyperbolicity. Support for such a view derives from the implied roots with very small imaginary parts, as discussed further below.

B.3 Discussion

To further explore the potential significance of the finding that failure to meet condition (B-20a) was consistently by an exceedingly small margin, we computed directly the eigenvalues (using MATHEMATICA (2008)), for a number of cases, an example of which is provided in Table B1. Such results allow us to generalize as follows:

- $\text{Re}(\lambda_1^*) \approx M^* + \hat{M}$ for $\hat{M} < 0.5$; $\text{Re}(\lambda_1^*) \approx M^* - \hat{M} + 1$ for $\hat{M} > 0.5$
- $\text{Re}(\lambda_2^*) \approx M^* + \hat{M}$ for all $\hat{M}$.
- $\lambda_3^* \approx M^* - \hat{M} - 1$ for all $\hat{M}$.
- $\lambda_4^* \approx M^* - \hat{M} + 1$ for $\hat{M} < 0.5$; $\lambda_4^* \approx M^* + \hat{M}$ for $\hat{M} > 0.5$

■ Table B1

A set of sample solutions of (B-15) with : $C = -3.3$, $\alpha_d = 0.1$, $\bar{\rho} = 1,000$

$\hat{M}$	M^*	λ_1^*	λ_2^*	λ_3^*	λ_4^*
0.1	0.38	0.48	0.48	-0.71	1.26
0.2	0.48	$0.68 + 0.001i$	$0.68 - 0.001i$	-0.71	1.26
0.3	0.58	$0.88 + 0.005i$	$0.88 - 0.005i$	-0.71	1.26
0.4	0.68	$1.10 + 0.012i$	$1.10 - 0.012i$	-0.71	1.26
0.5	0.78	$1.25 + 0.030i$	$1.25 - 0.030i$	-0.71	1.31
0.6	0.88	1.26	1.45	-0.71	1.50
0.7	0.98	1.26	1.65	-0.71	1.70

- The imaginary parts are always **at least** two orders of magnitude smaller than the real parts.

Moreover, using the definitions, we have the corresponding relations to the real speeds as follows:

$$M^* - \hat{M} - 1 = \frac{u_c - a_c}{a_c}, \quad M^* + \hat{M} = \frac{u_d}{a_c}, \quad \text{and} \quad M^* - \hat{M} + 1 = \frac{u_c + a_c}{a_c}.$$

In particular, when $\hat{M} \ll 0.5$ eigenvalues $\lambda_{1,2}$ are equal to u_d , recovering the result of the low Mach number analysis presented in ► Sect. B.1.

From the last bullet above, it is clear that the exceedingly small value of the discriminant can be associated with eigenvalues whose imaginary parts are very small in relation to their real parts. This in turn can be related to the stability character of our wave system (B-2), by recognizing that the unstable modes (those associated with the negative imaginary parts of the eigenvalues) grow with a characteristic time of $\tau_G = \chi/2\pi\lambda_i$ while the characteristic time for propagation is $\tau_P = \chi/2\pi\lambda_r$, where λ_i/λ_r are the imaginary/real parts of the corresponding eigenvalue, and χ is the wave length of the disturbance. Thus we have a measure of the “mild” non-hyperbolicity mentioned above as instability growth rates being slower than one-hundredth of disturbance propagation rates through our system. This, along with the fact in actual simulations the non-hyperbolic corridor would be traversed rather rapidly, suggest that our two-fluid model is effectively hyperbolic.

Appendix C: Including Surface Tension

Taking surface tension into account means upgrading the interfaces to the status of a third phase. As a consequence the interfaces have their own balance equations and they exchange mass, momentum, and energy with the two neighbor phases. Usually that third phase is supposed to have no mass and the surface tension γ is then a free energy depending on the mean temperature T_I of the interfaces. As a consequence the interfaces are endowed with an entropy

and an internal energy which, per unit volume of the mixture, are written as

$$S_I = -a_I \frac{d\gamma}{dT_I}, \quad U_I = a_I \left(\gamma - T_I \frac{d\gamma}{dT_I} \right) \quad (C-1)$$

where a_I is the density of interfacial area defined in (125). The thermodynamics of interfaces is made of the above definitions for energy and entropy together with the Gibbs relation

$$dU_I = T_I dS_I + \gamma da_I. \quad (C-2)$$

It is also usual to introduce a mean transport velocity V_I of the interfaces. That mean velocity is somehow arbitrary but whatever it is the above Gibbs relation can be transformed into a relation between transport equations that writes

$$\frac{\partial U_I}{\partial t} + \nabla \cdot (U_I V_I) = T_I \left[\frac{\partial S_I}{\partial t} + \nabla \cdot (S_I V_I) \right] + \gamma \left[\frac{\partial a_I}{\partial t} + \nabla \cdot (a_I V_I) \right]. \quad (C-3)$$

To simplify the issue the interfaces are supposed to have no momentum and no kinetic energy. Moreover, heat transport as well as viscous phenomena are neglected in that third phase. But the forces associated with surface tension are taken into account with an interfacial stress tensor

$$\sigma_I = - \langle \gamma (I - nn) \delta_I \rangle = a_I \gamma \left(C_{ij} - \frac{2}{3} I \right) \quad (C-4)$$

where the anisotropy tensor C_{ij} is defined in (127).

The main modification brought by surface tension to the two-fluid equations concerns the exchanges between the two phases. Except for mass exchanges they no longer mutually cancel. The sum of the two entropy exchanges is transformed into interfacial entropy and the sum of the two momentum exchanges is transformed into interfacial forces (interfacial stress in fact). But how the interfacial entropy and the interfacial stress are to be shared between the two phases? Let us solve that issue with the following trick: Instead of writing the balance equations for a quantity X in the form

$$\frac{dX_d}{dt} = x_d, \quad \frac{dX_c}{dt} = x_c, \quad \frac{dX_I}{dt} = -x_d - x_c \quad (C-5)$$

we incorporate the third equation into the first two with a “sharing” coefficient a and write

$$\frac{dX_d}{dt} = x - a \frac{dX_I}{dt}, \quad \frac{dX_c}{dt} = -x - (1-a) \frac{dX_I}{dt} \quad (C-6)$$

Doing so we can forget the third equation and obtain a set of equations very close to the one in the main text. In fact with two sharing coefficients a_s and a_u the two-fluid equations for entropy and momentum are modified into

$$\alpha_d \rho_d \frac{ds_d}{dt} + \alpha_d \nabla \cdot h = \Delta_d + \Sigma + \Gamma (s^* - s_d) - a_s \left[\frac{\partial S_I}{\partial t} + \nabla \cdot (S_I V_I) \right] \quad (C-7)$$

$$\alpha_c \rho_c \frac{ds_c}{dt} + \alpha_c \nabla \cdot h = \Delta_c - \Sigma - \Gamma (s^* - s_c) - (1-a_s) \left[\frac{\partial S_I}{\partial t} + \nabla \cdot (S_I V_I) \right] \quad (C-8)$$

$$\alpha_d \rho_d \frac{du_d}{dt} + \alpha_d \nabla \cdot \sigma + \alpha_d \nabla p_c = F + \Gamma (u^* - u_d) - a_u \nabla \cdot \sigma_I + \alpha_d \rho_d g \quad (C-9)$$

$$\alpha_c \rho_c \frac{du_c}{dt} + \alpha_c \nabla \cdot \sigma + \alpha_c \nabla p_c = -F - \Gamma (u^* - u_c) - (1-a_u) \nabla \cdot \sigma_I + \alpha_c \rho_c g. \quad (C-10)$$

Note that we neglected the interfacial entropy production like we did in the main text. Moreover, because they have no role in surface tension phenomena we simplified the issue by discarding all forces and stresses bound to velocity fluctuations but they can be restored without any problem. And we did not write the mass balances because they are not modified by massless interfaces. Repeating the procedure detailed in ► Sect. 3 we deduce from the above equations the transport equation for the total energy and we find

$$\begin{aligned} & \frac{\partial}{\partial t} (\alpha_d \rho_d E_d + \alpha_c \rho_c E_c) + \nabla \cdot (\alpha_d \rho_d E_d u_d + \alpha_c \rho_c E_c u_c + p_c u + u \cdot \sigma + T h) \\ &= (\alpha_d \rho_d u_d + \alpha_c \rho_c u_c) \cdot g + T_d \Delta_d + T_c \Delta_c + (T_d - T_c) \Sigma + (u_d - u_c) \cdot F \\ &+ \sigma : \nabla u + h \cdot \nabla T + \Gamma [\mu_d - \mu_c + (T_d - T_c) s^* + (u^* - u_c)^2/2 - (u^* - u_d)^2/2] \\ &+ (p_c - p_d) (\partial \alpha_d / \partial t + \nabla \cdot (\alpha_d u_d)) - T_I [\partial S_I / \partial t + \nabla \cdot (S_I V_I)] - W_I \cdot (\nabla \cdot \sigma_I) \end{aligned} \quad (C-11)$$

where

$$T_I = a_s T_d + (1 - a_s) T_c \quad (C-12)$$

$$W_I = a_u u_d + (1 - a_u) u_c. \quad (C-13)$$

Hence the mean interfacial temperature is connected to the sharing coefficient a_s and a mean interfacial velocity W_I can be defined, which is connected to the sharing coefficient a_u . That second interfacial velocity is bound to the power developed by interfacial forces and there is no reason for that velocity to be equal to the mean transport velocity V_I . The total energy is conserved and this imposes a very specific form for its evolution equation, which can be obtained with due account for (C-3) and which writes

$$\begin{aligned} & \frac{\partial}{\partial t} (\alpha_d \rho_d E_d + \alpha_c \rho_c E_c + U_I) + \nabla \cdot (\alpha_d \rho_d E_d u_d + \alpha_c \rho_c E_c u_c + U_I V_I) \\ &+ \nabla \cdot (p_c u + u \cdot \sigma + W_I \cdot \sigma_I + T h) = (\alpha_d \rho_d u_d + \alpha_c \rho_c u_c) \cdot g. \end{aligned} \quad (C-14)$$

As a consequence the total dissipation rate is

$$\begin{aligned} T_d \Delta_d + T_c \Delta_c &= (T_c - T_d) \Sigma + (u_c - u_d) \cdot F - h \cdot \nabla T + \Gamma [\mu_c - \mu_d \\ &+ (T_c - T_d) s^* - (u^* - u_c)^2/2 + (u^* - u_d)^2/2] - \sigma : \nabla u - \sigma_I : \nabla W_I \\ &+ (p_d - p_c) [\partial \alpha_d / \partial t + \nabla \cdot (\alpha_d u_d)] - \gamma [\partial a_I / \partial t + \nabla \cdot (a_I V_I)]. \end{aligned} \quad (C-15)$$

For dispersed mixtures plausible values for V_I and W_I are

$$V_I = u_d, \quad W_I = u, \quad (C-16)$$

meaning that the interfacial area is transported with the dispersed phase velocity and that the work of interfacial forces involves the volume-weighted velocity defined in (82), with the consequence that $a_u = \alpha_d$.

The two closures (C-16) have important consequences. The total stress of the suspension is $\sigma + \sigma_I + p_c I$. While σ_I is entirely proportional to the surface tension, a part of σ is also proportional to γ while the remaining part is a viscous stress τ^D . One is thus inclined to write

$$\sigma + \sigma_I = \alpha_d \left(p_d - p_c - \frac{2\gamma a_I}{3\alpha_d} \right) I - \tau^D - \tau^\gamma. \quad (C-17)$$

Closures for τ^D and τ^γ are given in (130) for the case of an emulsion. It is clear that τ^γ is different from the anisotropic part $a_I \gamma C_{ij}$ of σ_I . The last four terms of the dissipation rate (C-15) are then transformed into

$$\begin{aligned} & -(\sigma + \sigma_I) : \nabla u + (p_d - p_c) \left[\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right] - \gamma \left[\frac{\partial a_I}{\partial t} + \nabla \cdot (a_I u_d) \right] \\ & = \tau^D : D + \left(p_d - p_c - \frac{2\gamma a_I}{3\alpha_d} \right) \left[\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) - \alpha_d \nabla \cdot u \right] \\ & \quad - \gamma \left[\frac{\partial a_I}{\partial t} + \nabla \cdot (a_I u_d) - \frac{2a_I}{3\alpha_d} \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right) - \frac{\tau^\gamma}{\gamma} : D \right] \end{aligned} \quad (C-18)$$

where $D = (1/2)(\nabla u + \nabla u^T)$ is the suspension strain rate. The total dissipation rate is thus connected to the way one writes the transport equations for the volume fraction and the transport equation for the density of interfacial area.

Let us begin with the equation for α_d and the special case of bubbles moving in a noncompressible fluid. The starting point is

$$\begin{aligned} \frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) &= 3\alpha_d \frac{w_d}{a} + \frac{\Gamma}{\rho_d} \\ \frac{\partial \alpha_c}{\partial t} + \nabla \cdot (\alpha_c u_c) &= -\frac{\Gamma}{\rho_c}, \end{aligned} \quad (C-19)$$

where w_d is the radial velocity inside the bubble and close to its surface. w_d is related to the radial velocity w_c in the liquid close to the interface by the boundary condition (101) and we deduce from the two above equations $\nabla \cdot u = 3\alpha_d(w_c/a)$. Consequently

$$\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) - \alpha_d \nabla \cdot u = 3\alpha_d \alpha_c \frac{w_c}{a} + \frac{\Gamma}{\rho_c}, \quad (C-20)$$

a result equivalent to (100). That result also confirms that w_c is a much more convenient quantity to handle than w_d and that the transport equation for the volume fraction is more conveniently expressed as in (100) rather than in its more classical counterpart (C-19).

Concerning the density of interfacial area the above expression of the dissipation rate suggests to write its transport equation as

$$\frac{\partial a_I}{\partial t} + \nabla \cdot (a_I u_d) = \frac{2a_I}{3\alpha_d} \left(\frac{\partial \alpha_d}{\partial t} + \nabla \cdot (\alpha_d u_d) \right) + \frac{\tau^\gamma}{\gamma} : D - \Phi_\gamma, \quad (C-21)$$

where Φ_γ is a *positive* scalar reflecting the tendency of surface tension to decrease the total amount of interface. In (128) the $C : C$ term is a contribution to Φ_γ depicting the return to isotropic shapes. The coalescence phenomenon is represented by another contribution to Φ_γ . And the final expression of the dissipation rate is

$$\begin{aligned} T_d \Delta_d + T_c \Delta_c &= (T_c - T_d) \Sigma + (u_c - u_d) \cdot F - h \cdot \nabla T + \tau^D : D + \Gamma [\mu_c - \mu_d \\ &\quad + (T_c - T_d) s^* + (p_d - p_c - 2\gamma a_I / 3\alpha_d) / \rho_c - (u^* - u_c)^2 / 2 \\ &\quad + (u^* - u_d)^2 / 2] + 3\alpha_d \alpha_c (w_c / a) (p_d - p_c - 2\gamma a_I / 3\alpha_d) + \gamma \Phi_\gamma \end{aligned} \quad (C-22)$$

a result to be compared with (113).

PART II: COMPUTATION WITH EFFECTIVE-FIELD MODELS OF MULTIPHASE FLOWS

7 Introduction and Scope II

In Part II we pursue the EFM developed in Part I to its numerical implementation. To recapitulate, the principal desiderata are: robust and high-fidelity simulations of disperse systems at all flow speeds, and this implies, sharp capturing of pressure and flow discontinuities (shock waves), as well as highly resolved material (or contact) “interfaces.” Besides a well-founded numerical scheme, these aims require an ability to refine the grid (thereby requiring stability under reduced numerical dissipation), as well as the means to do so for problems involving large spatial dimensions, which in turn translates into a requirement for adaptive mesh refinement. The cornerstone to all these is a hyperbolic system of equations, which was shown to have been effectively achieved for all conditions of interest here (Part I). This allows for a focused treatment that is based on the extensive theoretical foundation of hyperbolic conservation laws (single-phase gas dynamics, Euler’s equations), as well as ample practical experience in aerospace science and engineering. Our main challenge then will be to extend these concepts and practice to the case where the flow field is occupied simultaneously (in the sense of interpenetrating continua) by more than one phase.

As we have seen in Part I, inviscid interactions (between the phases) play a critical role in securing the hyperbolic character of our system, and accordingly we can expect that the numerical treatment of these terms will be of central importance in adapting from the single-phase methods just mentioned. To further define the scope, it is sufficient for purposes of illustration (➤ Sect. 12) to consider disperse systems with continuous to disperse density ratios much less than unity (i.e., droplet or particle flows). This is because such flows: (a) make accessible large slip between the phases, and thusly supersonic regimes that are of great interest to our aims here, and (b) can exhibit inviscid interactions that are realistically and quantitatively significant. Notably, slip is rather small in bubbly flows, even under forced accelerations; for example, in converging/diverging channels breakup due to interfacial instabilities leads to decreased length scales and thus closely followed near-equilibrium. On the other hand, recall (Part I) that for bubbly flows we need to also include (to the system considered here) equations that describe radial inertia and volume fraction transport ((69)–(75) in Part I). The extension of the present treatment to such situations is rather straightforward. Other terms in the equations that describe dissipative phenomena due to viscosity, heat transfer between phases, phase change, and breakup/coalescence can be readily added as source terms in the equations – they are indicated in Part I at the basic level, and they do not affect the numerical treatment discussed here. In other words, they concern fidelity of a simulation in a particular venue rather than robustness of the numerical scheme.

Beyond this short introduction and the statement of our problem in (➤ Sect. 8, the presentation is arranged in three parts. The first part provides the foundations from single-phase flow as mentioned already – it is separated into two sections: (➤ Sect. 9 deals with theory and exact results, and (➤ Sect. 10 that leverages these essentially exact results to the most important approximate methods that address practical utility. The second part (➤ Sect. 11) provides the extension of these methods and ideas to the treatment of the EFM; that is to the development of the AUSM-ARMS scheme specifically tailored to our present needs. The third part (➤ Sect. 12) is on sample calculations that illustrate numerical performance. Throughout, we focus on

high-speed flows where the timescales are already limited by phenomena at the acoustic timescales and accordingly we limit our consideration to explicit schemes.

Our present focus provides the complement to moderate speed and incompressible flows already well known via the methods belonging to the ICE and SIMPLE families. Indeed, they are at the genesis of the CFD era, the Implicit Continuous-Fluid Eulerian (ICE) method by Harlow and Amsden (1968), at Los Alamos Scientific Laboratory, and the Semi-implicit Method for Pressure-Linked Equations (SIMPLE) by Patankar and Spalding (1972) at the Imperial College, UK (see also Harlow and Welch 1965). The former was the first method to overcome the Courant-Friedrichs-Lax (CFL) stability criteria, thus allowing practical simulations of large systems at all flow speeds (it formed the basis for all nuclear systems codes in existence to date – RELAP5, TRAC, CATHARE, etc.). The later is arguably one of the most popular methods for low/moderate Mach number flows, especially in commercial software packages. Other well-known multiphase flow codes that are based on the ICE method include KACHINA (Amsden and Harlow 1975), K-FIX (Rivard and Torrey 1997), and MF-ICE/MAC (Kashiwa and Rauenzahn 1994). The first CFD type codes used to assess steam explosion energetics in severe nuclear reactor accidents, PM-ALPHA-3D and ESPROSE-3D (Theofanous et al. 1998a,b), were based on the K-FIX solver. Commercial code packages that are based on SIMPLE include PHOENICS (Concentration Heat and Momentum Ltd.), FLUENT (Fluent Inc. joins ANSYS Inc.), and CFX (ANSYS Inc.).

8 Strategy for Computing Compressible Multi-Hydrodynamics

On the impetus of abounding gas dynamics problems, most notably from aerospace science and engineering, the numerical solution of hyperbolic conservation laws is well founded in theory (Lax 1954; Smoller 1983), and fully endowed in practice (Roe 1986; LeVeque 1990; Toro 1997), yet the supposedly similar path with multiphase systems has been filled with confusing retours and tangents. Starting with the first serious attempt at numerical simulation of nuclear reactor (loss of coolant) accidents, it was realized that coarse-graining of two-phase flows can be much more detrimental than that of turbulent flows – while they both share the issue of closure, re-incorporation of fine-scale physics lost in averaging, the mathematical character of the two-phase system was found to have lost the hyperbolic property. First pointed out by Gidaspow (1974), this “ill-posedness” implies that numerical solutions are inherently susceptible to catastrophic instability and much of the efforts since have been focused on:

- (a) Finding numerical schemes that improve resiliency – numerical dissipation being a leading method to such an end
- (b) Aiming to show that such instabilities, moderated by nonlinear effects and by dissipative (algebraic) “source terms” would not significantly contaminate the numerical results
- (c) Adding “by hand” closure terms that would restore hyperbolicity

On the other hand, and somewhat more severely, as a result of ill-posedness, there has been left some doubt on the basic correctness of the effective field model in any of the many shapes or forms that it has appeared in the literature (Drew and Passman 1999; Prosperetti and Satrape 1990; Prosperetti 1999).

On approaches (a) and (b) the major developments were made long ago and on behalf of the RELAP5 code – they have been invaluable for nuclear system simulations and are well documented in the open literature (RELAP5-3D Manuals 2006). The main ideas are that spatial discretizations normally employed in reactor system simulations introduce a sufficient amount of numerical dissipation to stabilize the solution, and that there is a “natural” cutoff on the unstable wave-numbers that is consistent with practical system discretization requirements (at least in terms of computer hardware available at the time). Furthermore, this dissipation role was shown to be aided by the drag terms in the momentum equations.

On item (c) the efforts have been of more widespread and diverse origins. The idea was to “constitute” the phase interaction terms that appear in the averaged momentum equations in a manner that includes the “added mass” and “interfacial pressure” mechanisms (collectively called inviscid interactions herein and in Part I). More specifically, these are to address the two pairs of terms involving stresses in (1) and (2) – the first and second terms on the RHS, where the χ and δ are the phase-indicator and interface-indicator functions respectively (see (1) and (2) of Part I).

$$\alpha_c \rho_c \frac{d_c \mathbf{u}_c}{dt} + \nabla \cdot \langle \chi_c \rho_c^0 \mathbf{v}'_c \otimes \mathbf{v}'_c \rangle = \nabla \cdot \langle \chi_c \boldsymbol{\sigma}_c^0 \rangle - \langle \boldsymbol{\sigma}_c^0 \cdot \mathbf{n}_d \delta_I \rangle + \alpha_c \rho_c \mathbf{g} \quad (133)$$

$$\alpha_d \rho_d \frac{d_d \mathbf{u}_d}{dt} + \nabla \cdot \langle \chi_d \rho_d^0 \mathbf{v}'_d \otimes \mathbf{v}'_d \rangle = \nabla \cdot \langle \chi_d \boldsymbol{\sigma}_d^0 \rangle + \langle \boldsymbol{\sigma}_c^0 \cdot \mathbf{n}_d \delta_I \rangle + \alpha_d \rho_d \mathbf{g} \quad (134)$$

In these equations subscripts c/d indicate continuous/disperse phases, respectively, $\boldsymbol{\sigma}$'s are phasic stresses, $\mathbf{u}$'s are velocities, ρ 's are densities, α 's are volume fractions, $\mathbf{v}'$'s are the pseudo-turbulent velocity fluctuations, and $\mathbf{n}_d$ is the unit vector normal to interface. The added mass, first introduced by Drew et al. (1979), is to account for accelerations of one phase relative to the other. The interfacial pressure, first introduced by Stuhmiller (1977), was visualized as a Bernoulli effect due to the continuous phase flowing “around” the individual elements of the dispersion. Stuhmiller's approach was found to be effective in rendering the system hyperbolic in incompressible, low-speed flows, and in fact it has been incorporated in the French nuclear code CATHARE (Bestion et al. 1999) (a descendant of RELAP5). Many followed with combinations and/or variations of these two “fixes,” however, this practical path did not appear to intersect with theory to an adequate degree, therefore lacking in definitiveness of treatment (Toumi et al. 1999). In particular, no definitive treatment can be found that is fully integrated with rigorous and complete developments of the effective field model, even though two such developments have become available long ago (Geurst 1985; Wallis 1991).

These two works (Geurst 1985; Wallis 1991) share with Part I the philosophy that rather than ad hoc and separate closures for added mass and interfacial pressure, inviscid interaction terms arise naturally and together with only minimal assumptions about the role of (pseudo-turbulent) velocity fluctuations. Perhaps more importantly, the results, which can be shown (Part I,  Sect. 6.1) to be in complete agreement among these three derivations, (135)–(140) below, include terms other than those that have come to be recognized as added mass and interfacial pressure. The impact of these terms on hyperbolicity is provided in Appendix B of Part I. Notably, the methodologies employed in these three independent derivations are completely different, and thus we believe that there is a high degree of reliability in the result.

Accordingly, this system is the starting point of our numerical treatment; (53)–(60) of Part I, with the gravity terms omitted without loss of generality, and allowing for compressibility of the

disperse phase:

$$\frac{\partial \alpha_c \rho_c}{\partial t} + \nabla \cdot (\alpha_c \rho_c \mathbf{u}_c) = 0 \quad (135)$$

$$\frac{\partial \alpha_d \rho_d}{\partial t} + \nabla \cdot (\alpha_d \rho_d \mathbf{u}_d) = 0 \quad (136)$$

$$\alpha_c \rho_c \frac{d_c \mathbf{u}_c}{d t} + \nabla \cdot \sigma_c^K + \alpha_c \nabla p_c = -\mathbf{F}^K \quad (137)$$

$$\alpha_d \rho_d \frac{d_d \mathbf{u}_d}{d t} + \nabla \cdot (\alpha_d P^K) + \alpha_d \nabla p_c = \mathbf{F}^K \quad (138)$$

$$\alpha_c \rho_c \frac{d_c E_c}{d t} + \nabla \cdot (\alpha_c p_c \mathbf{u}_c + \mathbf{u}_d \cdot \sigma_c^K) + p_c \frac{\partial \alpha_c}{\partial t} = -W^K \quad (139)$$

$$\alpha_d \rho_d \frac{d_d E_d}{d t} + \nabla \cdot (\alpha_d (p_c + P^K) \mathbf{u}_d) + p_c \frac{\partial \alpha_d}{\partial t} = W^K \quad (140)$$

Where:

$$E_c = e_c + \frac{1}{2} \mathbf{u}_c^2 + K_c; \quad K_c = \frac{1}{2} E(\alpha_d) (\mathbf{u}_d - \mathbf{u}_c)^2;$$

$$P^K = -\alpha_c \rho_c \frac{\partial K_c}{\partial \alpha_d}; \quad p_c = f(e_c, \rho_c); \quad \mathbf{J} = \alpha_c \rho_c E(\alpha_d) (\mathbf{u}_d - \mathbf{u}_c);$$

$$\mathbf{F}^K = -\frac{\partial \mathbf{J}}{\partial t} - \nabla \cdot (\mathbf{u}_d \otimes \mathbf{J}) - (\mathbf{J} \cdot \nabla) \mathbf{u}_c - \alpha_c \rho_c \nabla K_c - \mathbf{J} \times (\nabla \times \mathbf{u}_c)$$

$$E(\alpha_d) = \frac{1}{2} \alpha_d (1 + C \alpha_d); \quad W^K = \mathbf{u}_d \cdot \mathbf{F}^K + \alpha_d P^K \nabla \cdot \mathbf{u}_d; \quad \sigma_c^K = (\mathbf{u}_d - \mathbf{u}_c) \otimes \mathbf{J}$$

where p_c is the continuous phase pressure along with the definitions of other quantities as given above. The hyperbolicity analysis for this system will be used (► Sect. 11) in setting the finite volume rendition of this system and in the construction of our numerical scheme.

As established by the landmark papers of Lax (1954) and Courant et al. (1952) and summarized in an excellent review article by Roe (1986), “shock-capturing methods have attained mathematical respectability, partly through reinterpretation of the numerical equations as expressions of integral rather than differential laws, and partly through the incorporation of ideas drawn from the theory of characteristics.” The former refers to expressing spatial derivatives in complete divergence form, and by use of Gauss’ theorem to manifest these terms as flux differences at the boundaries of finite volumes (used to discretize our flow domain) – an overall effect of conservation is quite obvious. The later refers to estimating these fluxes so that “state information” is propagated correctly from the upstream and/or the downstream directions, according to the characteristic speeds of our flowing two-phase mixture (as we will see below, these involve both the flow speeds of the phases and their sound speeds) – this we call generically “**upwinding**.” In particular this opens up access to “**weak solutions**” (Lax, 1954), that is, it allows the existence of discontinuities such as shock waves or contact discontinuities, and the numerical challenge is to accomplish this robustly and without oscillations in the solution. This is expressed as the monotonicity preserving constraint, which however according to a theorem due to Godunov (1959) it is bound to be violated for any second- or higher-order accurate **linear** scheme. On the other hand, Godunov showed that first-order upwinding (see next section) is monotonicity preserving with the least truncation error, and this formed the

basis of a general strategy, namely to adding (carefully) EOS complexity and efficiency in computation. This strategy is also the foundation of our efforts in addressing the EFM. Accordingly, [Sects. 9](#) and [Sect. 10](#) are dedicated to setting up this foundation.

Now in the same vein we note that our system of equations cannot be set in a fully conservative form ([Sect. 11](#)). The “offending” terms are those involving the pressure gradient in the momentum equations as well as some of the terms representing inviscid interactions. More revealingly, the pressure gradient terms can be rewritten so that what is left outside the divergence sum are terms involving gradients in volume fractions – this is the real effect of “flow area” change for each of the phases, and in the extreme, it would represent a contact discontinuity (e.g., a gas flow entering a particle bed).

9 Basics: The Riemann Problem and the Godunov Method

Consider the motion of an (ideal) inviscid, compressible fluid in one space dimension. The “state” of fluid/motion at any point and time instant is described by the triplet [density, velocity, internal energy] = $[\rho, u, e]$, and the evolution from any initial state (a prescribed spatial distribution of these quantities) is governed by the conservation laws of mass, momentum, and energy – the latter follows from the requirement that, in the absence of shocks (these require special treatment), the entropy of such an ideal flow must remain constant. These are the Euler equations, which along with the fluid (thermodynamic) equation of state (EOS) write:

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}(\mathbf{U})}{\partial x} = 0, \quad t > 0, \quad -\infty < x < \infty, \quad E = e + \frac{1}{2} u^2, \quad e = e(\rho, p) \quad (141)$$

$$\mathbf{U} = (\rho, \rho u, \rho E)^T \text{ and } \mathbf{F}(\mathbf{U}) = [\rho u, \rho u^2 + p, (\rho E + p)u]^T$$

It can be seen that our EFM in the previous section reduces to the Euler equations when we let the disperse phase vanish. We will refer to the original triplet as “primitive” variables, while $\mathbf{U}$ expresses a vector of “conserved” variables. The idea of conservation derives from the recognition that by use of Gauss’ theorem the divergence of the fluxes, $\mathbf{F}(\mathbf{U})$, can be written as the net (signed) flux crossing the boundaries of our system (by convection and pressure forces). In numerical implementation this crucial property can be assured at the discrete level by simply defining quantities $\mathbf{U}$ as averages over finite (cell) volumes, and the quantities $\mathbf{F}(\mathbf{U})$ as some appropriately averaged fluxes over the cell boundaries.

For example, in one space dimension we can have our domain, say from $x = a$ to $x = b$, discretized by setting cell boundaries at $x_{j+1/2}$ ($j = 0, \dots, N$)

$$a = x_{1/2} < x_{3/2} < \dots < x_{N-1/2} < x_{N+1/2} = b \quad (142)$$

Accordingly we have cells (C_j), cell centers (x_j), and cell “volumes” (Δx_j), respectively as:

$$C_j \equiv [x_{j-1/2}, x_{j+1/2}], \quad x_j = \frac{1}{2} (x_{j-1/2} + x_{j+1/2}), \quad \Delta x_j = x_{j+1/2} - x_{j-1/2}. \quad (143)$$

On the time domain, we define

$$\mathcal{T}_n \equiv [t_n, t_{n+1}], \quad \Delta t \equiv t_{n+1} - t_n \quad (144)$$

Integration of (141) over $C_j \times \mathcal{T}_n$ gives

$$\int_{t_n}^{t_{n+1}} \frac{\partial}{\partial t} \left(\int_{x_{j-1/2}}^{x_{j+1/2}} \mathbf{U}(x, t) dx \right) dt + \int_{t_n}^{t_{n+1}} \int_{x_{j-1/2}}^{x_{j+1/2}} \frac{\partial \mathbf{F}(\mathbf{U}(x, t))}{\partial x} dx dt = 0 \quad (145)$$

which along with the definition for space and time averages:

$$\mathbf{u}_j^n \equiv \frac{1}{\Delta x_j} \int_{x_{j-1/2}}^{x_{j+1/2}} \mathbf{U}(x, t_n) dx \quad (146)$$

$$\mathbf{f}(x_{j+1/2}; t_n, t_{n+1}) \equiv \frac{1}{\Delta t} \int_{t_n}^{t_{n+1}} \mathbf{F}(\mathbf{U}(x_{j+1/2}, t)) dt \quad (147)$$

yields:

$$\Delta x_j \int_{t_n}^{t_{n+1}} \left(\frac{\partial}{\partial t} \mathbf{u}_j^n \right) dt + \int_{t_n}^{t_{n+1}} (\mathbf{F}(\mathbf{U}(x_{j+1/2}, t)) - \mathbf{F}(\mathbf{U}(x_{j-1/2}, t))) dt = 0 \quad (148)$$

If the fluxes in the above integral are evaluated at time t_{n+1} we have an implicit scheme. For our purposes it is sufficient to focus on explicit treatment, so then by dropping the t_n as well we finally have the discrete conservation law in terms of the approximate “numerical fluxes” at cell boundaries:

$$\mathbf{u}_j^{n+1} = \mathbf{u}_j^n - \frac{\Delta t}{\Delta x_j} (\mathbf{f}(x_{j+1/2}) - \mathbf{f}(x_{j-1/2})) \quad (149)$$

At this point it should be clear that the whole question is on how to deal with these approximate numerical fluxes so as to preserve the basic natural behavior of our system with maximum efficiency and fidelity. In particular, since the existence of weak (non-differentiable) solutions has been established theoretically, of special interest is to obtain such fluxes in the presence of discontinuities in state variables.

9.1 The Riemann Problem

Focusing on the problem of dealing with discontinuities, as introduced above, let us then consider the simplest case first, that of an infinite flow domain initially separated into two uniform states – we denote them by superscripts (or subscripts when it is more convenient) L/R (for the state on the left/right). Moreover, for illustration let us focus on a particular example of this general class of Riemann problems; the one exemplified by a shock tube allowing by release of a diaphragm to instantaneously contact two initially *stationary* states of a fluid found at two different pressure levels. Our object is to find the structure of the solution, and more specifically to determine the flux vector at the position of the diaphragm; taken at the origin, $x = 0$. With the notation introduced above, this flux vector is denoted as $\mathbf{f}(x = 0)$.

As illustrated in  Fig. 1, the solution consists of three principal wave fronts – they correspond to the three eigenvalues and propagate at constant rates that are related to the three characteristic speeds of our system, so in the x - t plane the front positions of these waves can be found for any future time as shown in the figure. The central wave indicated as “contact,” provides the material displacement from the original position of the diaphragm. Both pressures and velocities across this wave are continuous, but there is a density jump on account

■ Figure 1

Illustration of the solution structure to a Riemann (shock tube) problem. The solution is a constant on any “ray” (characteristics) emanating from the origin with a constant slope of x/t . The slopes of the characteristics that trace the wave fronts correspond to the eigenvalues

that on the left the fluid expands, while on the right it is compressed. This “material” characteristic speed is written as $\lambda_1 = u_R^* = u_L^* \equiv u^*$. The wave front on the left, marked as “rarefaction” propagates with the speed $\lambda_2 = u_L^* - a^*$, where a^* is the speed of sound in the compressed state. The situation of the wave front on the right marked as “shock,” is a little more complicated. If its amplitude is sufficiently small, it propagates with the characteristic speed $\lambda_3 = u_R^* + a^*$, otherwise such acoustic waves (as their speed increases with amplitude) would “pile up” into a shock, a singularity in pressure across which energy/entropy conservation cease to be observed – accordingly the speed of such a shock needs to be determined by simultaneous consideration of the mass, momentum, and energy conservation equations (the so-called Rankine-Hugoniot (R-H) relations). The details are readily available and beyond our specific purposes here, but suffice to note that:

1. The characteristic speeds introduced above, the λ ’s, are called the eigenvalues. For their explicit connection to (141) and ► Fig. 1, and their further utility in our task it is best to wait until ► 10.1.
2. The nonlinearity (increasing/decreasing sound speed with state of compression/expansion) that steepens the compression front to a shock is responsible for “flattening” (with time)

the rarefaction (at the other end) through a fan of wave “fronts” all emanating from the origin.

3. The R-H conditions on the shock and an isentropic expansion on the rarefaction allow starred quantities to be related to the initial L/R states, $\mathbf{U}_L; \mathbf{U}_R$, and these relationships along with the requirement that pressures and velocities are continuous across the contact discontinuity (note also the possibility of two different fluids involved in the use of EOS), yield an algebraic system to be solved (for the starred quantities) as the actual quantitative solution. This is the exact solution to the Riemann problem under consideration.
4. Once this solution is known, the sought-after flux at the origin is obtained simply as:

$$\mathbf{f}(x = 0, t) = \begin{cases} \mathbf{f}(\mathbf{U}_L^*; \mathbf{U}_R^*) = \mathbf{f}(\mathbf{U}_L^*) & \text{if } u^* \geq 0 \\ \mathbf{f}(\mathbf{U}_L^*; \mathbf{U}_R^*) = \mathbf{f}(\mathbf{U}_R^*) & \text{if } u^* < 0 \end{cases} \quad (150)$$

where the notation $\mathbf{f}(\mathbf{U}_L^*; \mathbf{U}_R^*)$ is to express the flux at the origin (the position of the diaphragm). As is to be seen in [► 9.2](#), this is a major result in motivating the concept of “upwinding.”

It is important to note that in general the initial state of a Riemann problem will involve nonzero velocities – they would enter in the determination of the starred quantities, and in particular in the upwinding criterion (150) – in the particular shock tube example given above $u^* > 0$ obviously, but this is not to be so in general. Also note that since there is no characteristic length or time scales imposed, the solution to our problem depends solely on the combination x/t . Lines of constant x/t are called characteristics and the solution remains constant along a characteristic. Accordingly, the space between wave fronts is described by uniform states, except in the case of an expansion, where the “front” broadens out with time ([► Fig. 1](#)).

Godunov (1959) capitalized on these simple ideas to propose a general numerical scheme capable of predicting evolutions from any initial state $\mathbf{U}_0(x)$, even when this initial distribution contains singularities. Moreover, even though the exact Riemann solution is not available for flows in higher dimensions, this numerical concept could be extended to provide robust and accurate results as summarized in [► 9.2](#) and [► 10.3](#). In turn these provide the cornerstone for our own developments in regards to the EFM ([► Sect. 11](#)).

9.2 The Godunov Method

Godunov’s brilliant and path-breaking idea was to provide the exact solution to an *approximation* of the initial fluid state “decomposed” in such a manner as to conform to a series of Riemann problems as illustrated in [► Fig. 2](#) – in the simplest, first-order approximation, the decomposition is in terms of piece-wise constant values. Now according to notation introduced already, the $\mathbf{u}_j^n$ ’s represent cell-average values of the “initial” state function in positions j at time cycle n , and the fluxes based on the Riemann problem across any two cells say $[j, j+1]$ are then denoted by $\mathbf{f}(x_{j+1/2}) = \mathbf{f}(\mathbf{u}_{j+1/2}^L, \mathbf{u}_{j+1/2}^R)$. Thus, the average values at each cell in the next time increment Δt can be simply written out according to (149) as:

$$\begin{aligned} \mathbf{u}_j^{n+1} &= \mathbf{u}_j^n - \frac{\Delta t}{\Delta x_j} \left(\mathbf{f}(\mathbf{u}_{j+1/2}^L, \mathbf{u}_{j+1/2}^R) - \mathbf{f}(\mathbf{u}_{j-1/2}^L, \mathbf{u}_{j-1/2}^R) \right) \\ &\equiv \mathbf{u}_j^n - \frac{\Delta t}{\Delta x_j} \left(\mathbf{f}(\mathbf{u}_j, \mathbf{u}_{j+1}) - \mathbf{f}(\mathbf{u}_{j-1}, \mathbf{u}_j) \right) \end{aligned} \quad (151)$$

■ Figure 2

Illustration of the reduction of a general Euler governed problem to the solution of a series of Riemann problems – first-order approximation

■ Figure 3

Illustration of the Godunov reduction in terms of higher-order approximations to a series of Riemann problems

For higher-order approximation the Riemann problems are defined in terms of states extrapolated from “sided” interpolations as illustrated in ► Fig. 3.

In two or three dimensions, the procedures are very similar, as boundary fluxes are composed from appropriately defined, one-dimensional Riemann problems at each of the cell boundaries. Details on practical implementation of the Godunov method can be found in van Leer (1979), Colella and Glaz (1985), LeVeque (1990), and Toro (1997).

A recent example of the fundamental and broad reach of the Riemann solution is a particular implementation at the interface between two different fluids with high acoustic impedance mismatch – it brings the accuracy and robustness of front-tracking approach into the fast local level set front-capturing implementation of the characteristics-based matching (CBM) method (Nourgaliev et al. 2006), and further on to ab initio capturing of interfacial instabilities by the Sharp Interface Method (SIM) (Nourgaliev and Theofanous 2007; Nourgaliev et al. 2008; Chang et al. 2010b).

What remains to be done is to overcome the issues of inefficiency inherent in the method: the solution of a nonlinear set of algebraic equations by iteration methods, which is further

aggravated in the case of complex EOS (nonideal, stiffened gas, etc.). However, the Godunov method remains the “gold standard” in testing such other approaches.

10 Approximate Flux “Splitting” Schemes for Single Phase Flows

Three critical approaches in “translating” Godunov’s idea to practicality are outlined here. All three involve some sort of flux splitting aimed to “mimic” the characteristics-inspired “upwinding” discussed above but *without* solving the exact Riemann problem. In the first approach (flux difference splitting, or FDS), due to Roe (1981), this is accomplished by recasting the exact mathematical statement of the Riemann (eigenvalue) problem involved into an approximate (linearized) one whose solution can be obtained in a form convenient for numerical implementation. In the second approach (flux vector splitting, or FVS), due to van Leer (1982), the eigenvalue problem is bypassed altogether by means of a Mach-based flux splitting that provides exact upwinding for supersonic conditions and an approximate interpolation for the intermediate subsonic region. The third approach (advection upstream splitting method, or AUSM), due to Liou and Steffen (1993) and Liou (1996), is a hybrid that combines the following specific features inherent to the first two: (1) property of FVS that selects only entropy satisfying approximate solutions (it can distinguish between expansions and shocks), and (2) decisive ability of some FDS methods to exactly capture stationary contact discontinuities and shocks. Indeed, the role of the convection cannot be overstated – it is the process that embodies the nonlinear effects of Euler equations, which can turn initially smooth profiles sharper and eventually into discontinuities (shocks). Along with a summary description of each of these approaches below we provide the successive improvements achieved.

The figures of merit in this evaluation can be listed as follows:

- Discontinuity (shocks, contacts, expansions) capturing, stationary or moving, at all flow speeds
- Monotonicity preserving (not prone to spurious oscillations near discontinuities)
- Positivity preserving (thermodynamic and material parameters remaining nonnegative)

Clearly the aim is to achieve simultaneously all of the above in the most efficient computational manner and with maximum scope of application (generality). Maintaining conservation and satisfying appropriate entropy criteria are not to be sacrificed while trying to meet these ends. At a more philosophical level, the success of Godunov’s idea of using an exact solution to an approximation of the actual problem compels to further approximations in solving this Riemann problem itself.

10.1 Characteristics-Based Flux Splitting

Consider a Riemann problem, as the one in  Fig. 1, but now let us suppose that we “resolve” the discontinuities in the manner illustrated in  Fig. 4; that is, the fluxes associated with each of the three waves are thought to be decomposed into a series of infinitesimal fluxes, $\delta \mathbf{f}_k$, $k = 1, 2$ or 3 each associated with an incremental (infinitesimal) wave amplitude. In terms of our

■ **Figure 4**
Illustration of Roe's flux difference-based splitting

Jacobian matrix ($\mathbf{A}$), the three eigenvalues ($\lambda_1, \lambda_2, \lambda_3$) arranged along the diagonal of Λ , and the eigenmatrix $\mathbf{R}$ and its inverse matrix $\mathbf{L} \equiv \mathbf{R}^{-1}$, the decomposition can be written as:

$$\begin{aligned}
 \delta \mathbf{F} &= \frac{\partial \mathbf{F}}{\partial \mathbf{U}} \delta \mathbf{U} = \mathbf{A} \delta \mathbf{U} = \mathbf{R} \Lambda \mathbf{L} \delta \mathbf{U} \\
 &= \mathbf{R} \begin{pmatrix} \lambda_1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \mathbf{L} \delta \mathbf{U} + \mathbf{R} \begin{pmatrix} 0 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \mathbf{L} \delta \mathbf{U} + \mathbf{R} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \lambda_3 \end{pmatrix} \mathbf{L} \delta \mathbf{U} \\
 &= \mathbf{R} \Lambda_1 \mathbf{L} \delta \mathbf{U} + \mathbf{R} \Lambda_2 \mathbf{L} \delta \mathbf{U} + \mathbf{R} \Lambda_3 \mathbf{L} \delta \mathbf{U} \equiv \delta \mathbf{f}_1 + \delta \mathbf{f}_2 + \delta \mathbf{f}_3
 \end{aligned} \tag{152}$$

So the fluxes evaluated at the right and left states differ by:

$$\begin{aligned}
 \mathbf{F}(\mathbf{U}_R) - \mathbf{F}(\mathbf{U}_L) &= \int_{\mathbf{U}_L}^{\mathbf{U}_R} \mathbf{A} d\mathbf{U} \\
 &= \int_{\mathbf{U}_L}^{\mathbf{U}_R} \mathbf{R} \Lambda_1 \mathbf{L} d\mathbf{U} + \int_{\mathbf{U}_L}^{\mathbf{U}_R} \mathbf{R} \Lambda_2 \mathbf{L} d\mathbf{U} + \int_{\mathbf{U}_L}^{\mathbf{U}_R} \mathbf{R} \Lambda_3 \mathbf{L} d\mathbf{U} \\
 &\equiv \Delta \mathbf{f}_1 + \Delta \mathbf{f}_2 + \Delta \mathbf{f}_3
 \end{aligned} \tag{153}$$

which also shows that the sign of each λ_k carries over to the sign of $\Delta \mathbf{f}_k$:

$$(\Delta \mathbf{f}_k)^\pm = \frac{1}{2} \int_{\mathbf{U}_L}^{\mathbf{U}_R} \mathbf{R} (\Lambda_k \pm |\Lambda_k|) \mathbf{L} d\mathbf{U} \tag{154}$$

Moreover, (153) provides the path to smoothly connect the fluxes across the two neighboring cells by means of the three incremental *characteristic* fluxes. In particular, using upwinding the Riemann flux at the cell boundary can be expressed by any of the three forms

(see also  Fig. 4):

$$\begin{aligned}
 \mathbf{F}(\mathbf{U}_L, \mathbf{U}_R) &= \mathbf{F}(\mathbf{U}_L) + \sum_k (\Delta \mathbf{f}_k)^- \\
 &= \mathbf{F}(\mathbf{U}_R) - \sum_k (\Delta \mathbf{f}_k)^+ \\
 &= \frac{1}{2} \left[\mathbf{F}(\mathbf{U}_L) + \mathbf{F}(\mathbf{U}_R) + \sum_k (\Delta \mathbf{f}_k)^- - \sum_k (\Delta \mathbf{f}_k)^+ \right]
 \end{aligned} \tag{155}$$

So far these formal results are exact and not of much help in computation since the integrations in (153) are over a continuously changing eigensystem. Roe's idea was to replace the whole series of $\mathbf{A}$'s seen in the above derivation as one traverses from state $\mathbf{U}_L$ or $\mathbf{U}_R$ toward the common cell boundary, by one effective $\mathbf{A}$. This he accomplished by evaluating $\mathbf{A}$ at some appropriately chosen "intermediate" state, $\tilde{\mathbf{U}} = \tilde{\mathbf{U}}(\mathbf{U}_L, \mathbf{U}_R)$, so that $\tilde{\mathbf{A}}(\mathbf{U}_L, \mathbf{U}_R) = \mathbf{A}(\tilde{\mathbf{U}}(\mathbf{U}_L, \mathbf{U}_R))$ satisfies the following:

1. Matrix $\tilde{\mathbf{A}}$ has real eigenvalues and a complete set of eigenvectors (hyperbolicity)
2. $\mathbf{F}(\mathbf{U}_R) - \mathbf{F}(\mathbf{U}_L) = \tilde{\mathbf{A}}(\mathbf{U}_L, \mathbf{U}_R) (\mathbf{U}_R - \mathbf{U}_L)$ so that conservation can be ensured
3. $\tilde{\mathbf{A}}(\mathbf{U}, \mathbf{U}) = \mathbf{A}(\mathbf{U})$ for consistency

So now in place of (153) and (155) we have, respectively:

$$\begin{aligned}
 \mathbf{F}(\mathbf{U}_R) - \mathbf{F}(\mathbf{U}_L) &= \tilde{\mathbf{A}} \Delta \mathbf{U} \\
 &= \tilde{\mathbf{R}} \tilde{\Lambda}_1 \tilde{\mathbf{L}} \Delta \mathbf{U} + \tilde{\mathbf{R}} \tilde{\Lambda}_2 \tilde{\mathbf{L}} \Delta \mathbf{U} + \tilde{\mathbf{R}} \tilde{\Lambda}_3 \tilde{\mathbf{L}} \Delta \mathbf{U} \\
 &= \Delta \mathbf{f}_1 + \Delta \mathbf{f}_2 + \Delta \mathbf{f}_3
 \end{aligned} \tag{156}$$

$$\begin{aligned}
 \mathbf{F}(\mathbf{U}_L, \mathbf{U}_R) &= \mathbf{F}(\mathbf{U}_L) + \tilde{\mathbf{A}}^- (\mathbf{U}_R - \mathbf{U}_L) \\
 &= \mathbf{F}(\mathbf{U}_R) - \tilde{\mathbf{A}}^+ (\mathbf{U}_R - \mathbf{U}_L) \\
 &= \frac{1}{2} [\mathbf{F}(\mathbf{U}_L) + \mathbf{F}(\mathbf{U}_R) - |\tilde{\mathbf{A}}| (\mathbf{U}_R - \mathbf{U}_L)]
 \end{aligned} \tag{157}$$

where $|\tilde{\mathbf{A}}| = \tilde{\mathbf{A}}^+ - \tilde{\mathbf{A}}^-$ is a quantity related to the numerical dissipation. Due to the form of these equations Roe's method is referred as Flux Difference Splitting (FDS).

To illustrate, for an ideal gas, the flux Jacobian matrix is (with γ being the ratio of specific heats):

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 0 \\ -(3-\gamma)\frac{u^2}{2} & (3-\gamma)u & \gamma-1 \\ (\gamma-1)u^3 - \gamma u E & \gamma E - \frac{3}{2}(\gamma-1)u^2 & \gamma u \end{pmatrix} \tag{158}$$

The eigenvalues and eigenvectors can be obtained analytically as:

$$\Lambda = \begin{pmatrix} u & 0 & 0 \\ 0 & u-a & 0 \\ 0 & 0 & u+a \end{pmatrix} \tag{159}$$

$$\mathbf{R} = \begin{pmatrix} 1 & -\frac{\rho}{2a} & \frac{\rho}{2a} \\ u & -\frac{\rho}{2a}(u-a) & \frac{\rho}{2a}(u+a) \\ \frac{u^2}{2} & -\frac{\rho}{2a}\left(\frac{u^2}{2} - ua + \frac{a^2}{\gamma-1}\right) & \frac{\rho}{2a}\left(\frac{u^2}{2} + ua + \frac{a^2}{\gamma-1}\right) \end{pmatrix} \quad (160)$$

$$\mathbf{L} = \begin{pmatrix} 1 - \frac{\gamma-1}{2} \frac{u^2}{a^2} & (\gamma-1) \frac{u}{a^2} & -\frac{\gamma-1}{a^2} \\ -\frac{1}{\rho a} \left(\frac{\gamma-1}{2} u^2 + ua \right) & \frac{1}{\rho a} (a + (\gamma-1)u) & -\frac{\gamma-1}{\rho a} \\ \frac{1}{\rho a} \left(\frac{\gamma-1}{2} u^2 - ua \right) & \frac{1}{\rho a} (a - (\gamma-1)u) & \frac{\gamma-1}{\rho a} \end{pmatrix} \quad (161)$$

Then from the condition 2 the Roe-“average” state $\tilde{\mathbf{U}}$ can be found analytically:

$$\tilde{\rho} = \sqrt{\rho_L \rho_R}, \tilde{u} = \frac{u_L \sqrt{\rho_L} + u_R \sqrt{\rho_R}}{\sqrt{\rho_L} + \sqrt{\rho_R}}, \tilde{H} = \frac{H_L \sqrt{\rho_L} + H_R \sqrt{\rho_R}}{\sqrt{\rho_L} + \sqrt{\rho_R}}, H = E + \frac{p}{\rho} \quad (162)$$

Finally, the numerical flux for Roe’s approximate Riemann solver can be calculated by (157).

Remarks on performance:

1. Condition (2) also ensures that the Rankine-Hugoniot conditions, relating the speed s of a single discontinuity (contact or shock) to the jump across it, is satisfied, namely:

$$\mathbf{F}(\mathbf{U}_R) - \mathbf{F}(\mathbf{U}_L) = s (\mathbf{U}_R - \mathbf{U}_L)$$

This together with condition (2) gives:

$$\tilde{\mathbf{A}} (\mathbf{U}_R - \mathbf{U}_L) = s (\mathbf{U}_R - \mathbf{U}_L) \quad \text{Or} \quad \tilde{\mathbf{A}} - s \mathbf{I} = 0$$

which shows that s is an eigenvalue of the Roe matrix $\tilde{\mathbf{A}}$; namely that $s = \tilde{u} + \tilde{a}$ ($\tilde{u} > 0$) or $s = \tilde{u}$. Clearly therefore, any two states that are “connected” by the Rankine-Hugoniot condition can be resolved by Roe’s approximate Riemann solver exactly (provided the grid moves along with the discontinuity), and stationary discontinuities can be captured in principle exactly. In practice however, the scheme is known to fail for super strong shocks (both in 1D and 2D) even if stationary (Kitamura et al. 2007), and also performance deteriorates (oscillations) in slow-moving shocks. Moving contact discontinuities can in principle be captured exactly at the CFL = 1 limit (► 10.2), but this is not useful for practice, and the scheme is diffusive.

2. The downside of this exact property of Roe splitting is that it cannot distinguish between a shock and an expansion wave – that is, the splitting does not satisfy the entropy condition, a difficulty that leads to nonphysical jump within the expansion wave, known as “expansion shock.” This occurs because one of the eigenvalues decreases toward a zero value and concomitantly the numerical dissipation gradually disappears too. To remedy the problem, one needs to impose a lower limitation on the absolute magnitude of the eigenvalue. This procedure generally known as “entropy fix” was first suggested by Harten and Hyman (1983) and has several variants now.

3. For nonideal gas the eigenvalues are the same (with the speed of sound obtained from the applicable EOS), but the eigenvectors are not, and the Roe-“average” is not unique (Liou et al. 1990; Shuen et al. 1990).
4. Finally the method is susceptible to the so-called carbuncle instability – a transverse instability in 2D or 3D shocks that will be illustrated in [10.3](#).

10.2 Direct Flux Splitting

Direct flux splitting began with Steger and Warming’s (1981) idea that, for the Euler system, the flux vector $\mathbf{F}(\mathbf{U})$ is a linearly homogenous function of degree one in $\mathbf{U}$ and accordingly:

$$\mathbf{F} = \frac{\partial \mathbf{F}(\mathbf{U})}{\partial \mathbf{U}} \mathbf{U} \equiv \mathbf{A} \mathbf{U} \quad (163)$$

Thus following the same diagonalization procedure as applied previously to $\delta \mathbf{F}$ (Roe), we can now split $\mathbf{F}$ directly into components associated respectively with the positive and negative eigenvalues:

$$\mathbf{F} = \mathbf{R} \mathbf{\Lambda} \mathbf{L} \mathbf{U} \equiv \mathbf{R} (\mathbf{\Lambda}^+ + \mathbf{\Lambda}^-) \mathbf{L} \mathbf{U} \equiv (\mathbf{A}^+ + \mathbf{A}^-) \mathbf{U} \equiv \mathbf{F}^+ + \mathbf{F}^- \quad (164)$$

Thus, the numerical flux at the cell boundary can be expressed as:

$$\mathbf{F}(\mathbf{U}_L, \mathbf{U}_R) = \mathbf{F}^+(\mathbf{U}_L) + \mathbf{F}^-(\mathbf{U}_R) \quad (165)$$

which automatically gives the exact flux at supersonic conditions:

1. If $M_L > 1$ and $M_R > 1$, then $\mathbf{F}^+(\mathbf{U}_L) = \mathbf{F}(\mathbf{U}_L)$ and $\mathbf{F}^-(\mathbf{U}_R) = 0$;
If $M_L < -1$ and $M_R < -1$, then $\mathbf{F}^-(\mathbf{U}_R) = \mathbf{F}(\mathbf{U}_R)$ and $\mathbf{F}^+(\mathbf{U}_L) = 0$.
2. All the eigenvalues of matrices $\frac{\partial \mathbf{F}^+(\mathbf{U})}{\partial \mathbf{U}} / \frac{\partial \mathbf{F}^-(\mathbf{U})}{\partial \mathbf{U}}$ are nonnegative/nonpositive.
3. $\mathbf{F}(\mathbf{U}, \mathbf{U}) = \mathbf{F}^+(\mathbf{U}) + \mathbf{F}^-(\mathbf{U})$ for consistency.

The problem with this procedure is that the eigenvalues of $\mathbf{A}$ do not carry over individually to the splitted Jacobians; that is:

$$\mathbf{A} \equiv \frac{\partial \mathbf{F}}{\partial \mathbf{U}} \equiv \frac{\partial \mathbf{F}^+}{\partial \mathbf{U}} + \frac{\partial \mathbf{F}^-}{\partial \mathbf{U}} \equiv \mathbf{A}^+ + \mathbf{A}^- \text{ does \textit{not} imply } \frac{\partial \mathbf{F}^+}{\partial \mathbf{U}} = \mathbf{A}^+ \text{ and } \frac{\partial \mathbf{F}^-}{\partial \mathbf{U}} = \mathbf{A}^-$$

and the consequence in practical terms is that the zero eigenvalues expected in the splitting of $\mathbf{A}$ may now become small positive/negative values, thereby “contaminating” upwinding, which can become particularly problematic in subsonic flow. Moreover, while the splitting in (164) yields automatically proper fully one-sided upwinding at the sonic points $|u| = a$, the switching is not differentiable, thereby resulting in glitches there, even in a smooth acceleration from subsonic to supersonic speeds. The discontinuous switching also adds more dissipation at shock points than other flux schemes such as presented in this article.

Independent work by van Leer (1982) anticipated this switching difficulty and specifically required that the Jacobians of split fluxes be differentiable at sonic point. In addition, he sought to have one eigenvalue vanish identically so that the shock is captured in two cells. To achieve this he proposed to interpolate the splitting between the two extremes (upwinding) specified

■ Figure 5

The interpolation of Mach split function used in van Leer's approach to subsonic flow

above for supersonic flow. More specifically, as indicated in ► Fig. 5, in the intermediate subsonic region one operates with a combination of both nonlinear fields characterized by $u + a > 0$ and $u - a < 0$, namely $M = \mathcal{M}^+(M) + \mathcal{M}^-(M)$. Formally, the additional conditions imposed are:

4. $\frac{\partial \mathbf{F}^\pm}{\partial U}$ must be continuous and have one zero eigenvalue if $|M| < 1$.
5. The $\mathbf{F}^+ / \mathbf{F}^-$ must be symmetric in M ; $\mathbf{F}^+(M) = \mathbf{F}^-(-M)$; $\mathbf{F}^-(M) = \mathbf{F}^+(-M)$.

We will build, according to van Leer, the vector $\mathbf{f}$ for this subsonic region from its components (f_1, f_2, f_3) corresponding to the conserved variables (mass, momentum, energy), considered one by one separately. Moreover, we will use this as a way to anticipate and to bridge with AUSM – accordingly the derivation acknowledges AUSM's key physics-based idea of separating out (and treating accordingly) convective from pressure contributions to the flux vector.

From the continuity equation we have:

$$\begin{aligned} f_1 &= \rho u = \rho a M \\ &\equiv \rho a (\mathcal{M}^+(M) + \mathcal{M}^-(M)). \\ &\equiv f_1^+ + f_1^- \end{aligned} \quad (166)$$

When $M > 1$, we have $f_1^+ = f_1$ and $f_1^- = 0$, giving that $\mathcal{M}^+(M) = M$ and $\mathcal{M}^-(M) = 0$. Similarly, when $M < -1$, we have $\mathcal{M}^+(M) = 0$ and $\mathcal{M}^-(M) = M$. For the interpolation van Leer used:

$$\mathcal{M}_{(2)}^\pm(M) = \pm \frac{1}{4} (M \pm 1)^2 \quad (167)$$

where subscript “(2)” is to indicate the order of the polynomial employed. The numerical mass flux can then be written as:

$$(f_1)_{1/2} = \rho_L a_L \mathcal{M}_{(2)}^+(M_L) + \rho_R a_R \mathcal{M}_{(2)}^-(M_R) \quad (168)$$

For the momentum equation similarly, with the incorporation of splitting, we have:

$$\begin{aligned}
 f_2 &= \rho u^2 + p \\
 &= \rho a^2 \left(M^2 + \frac{1}{\gamma} \right) \\
 &= \frac{1}{4} \rho a^2 (M+1)^2 \left(M + \frac{1}{\gamma} (2-M) \right) + \frac{1}{4} \rho a^2 (M-1)^2 \left(-M + \frac{1}{\gamma} (2+M) \right) \\
 &\equiv f_2^+ + f_2^-
 \end{aligned} \tag{169}$$

Which accordingly can be seen in more familiar terms to be:

$$\begin{aligned}
 f_2^\pm &= \pm (\rho u) a \cdot \frac{1}{4} (M \pm 1)^2 + p \cdot \frac{1}{4} (M \pm 1)^2 (2 \mp M) \\
 &= (\rho u) a \cdot \mathcal{M}_{(2)}^\pm(M) + p \cdot \mathcal{P}_{(3)}^\pm(M)
 \end{aligned} \tag{170}$$

with the interpolated pressure split function (illustrated in  Fig. 6):

$$\mathcal{P}_{(3)}^\pm(M) = \frac{1}{4} (M \pm 1)^2 (2 \mp M) \tag{171}$$

Lastly, by combination of the above we obtain the splitting for energy flux:

$$\begin{aligned}
 f_3^\pm &= \frac{\gamma^2}{2(\gamma^2 - 1)} \frac{(f_2^\pm)^2}{f_1^\pm} \\
 &= \pm \frac{\rho a}{4} (M \pm 1)^2 \cdot \frac{2a^2}{\gamma^2 - 1} \left(1 \pm \frac{\gamma - 1}{2} M \right)^2 \\
 &= f_1^\pm (H - m(u \mp a))
 \end{aligned} \tag{172}$$

 Figure 6

The interpolation of pressure split function used in van Leer's approach to subsonic flow

with

$$m = \frac{h}{a^2 + 2h} \quad (173)$$

so that the square bracket in the energy flux can be factored into a perfect square for an ideal gas. This results in a nice property that one eigenvalue of the split-flux Jacobians vanishes, thus leading to reduced numerical dissipation and sharper resolution of shocks (van Leer 1982). This property however is hard to maintain for a general gas.

To summarize, the splitted flux vector can be written so as to visualize not only the upwinding, but also the splitting between the convection and pressure components:

$$\mathbf{f}^\pm = a \mathcal{M}_{(2)}^\pm(M) \begin{pmatrix} \rho \\ \rho u \\ \rho H - \rho m(u \mp a) \end{pmatrix} + \begin{pmatrix} 0 \\ p \mathcal{P}_{(3)}^\pm(M) \\ 0 \end{pmatrix} \quad (174)$$

In this form van Leer's method is not able to maintain constant total enthalpy along a streamline. One simple "fix" derived independently in Hänel et al. (1987) and Shuen et al. (1990), is to drop the term $\rho m(u \mp a)$. Thus in final form the recommended van Leer splitting of the Riemann flux is:

$$\begin{aligned} \mathbf{f}_{1/2}(\mathbf{U}_L, \mathbf{U}_R) &= a_L \mathcal{M}_{(2)}^+(M_L) \Phi_L + a_R \mathcal{M}_{(2)}^-(M_R) \Phi_R \\ &+ \begin{pmatrix} 0 \\ p_L \mathcal{P}_{(3)}^+(M_L) + p_R \mathcal{P}_{(3)}^-(M_R) \\ 0 \end{pmatrix} \end{aligned} \quad (175)$$

with $\Phi = (\rho, \rho u, \rho H)^\top$.

It is observed that the whole splitting hinges on the split Mach numbers $\mathcal{M}^\pm$, which defines the mass and pressure fluxes, which in turn affects the momentum and energy fluxes.

Remarks on Performance

1. It turns out that this flux vector splitting is significantly easier to implement in comparison to Roe's scheme of building numerical fluxes, and surprisingly, it possesses a good capability of capturing shocks.
2. In addition to the advantage of being smooth at the transition points where eigenvalues change signs, this splitting does not involve differentiation of flux functions with respect to $\mathbf{U}$ (it does not involve the Jacobian). Instead, the imprint of the EOS appears covertly (via the speed of sound), the key parameter is the Mach number, and the form of split fluxes remains the same for all types of EOS. This point becomes a tremendous advantage in computing multiphase flows. Moreover, this splitting, being in terms of mass fluxes only, allows any additional conservation laws to be easily added making extensions to other kinds of systems rather straightforward.
3. As pointed out by van Leer himself, the dispensing with the eigensystem undermines the scheme's performance in regards to contact discontinuities as can be seen in the following: Consider a moving contact discontinuity defined as:

$$\rho_j = \begin{cases} \rho_1 & \text{for } j < k \\ \rho_2 & \text{for } j \geq k+1 \end{cases} \quad u_j = u^* \geq 0, p_j = p^*$$

From [10.1, \(157\)](#), we can readily see that Roe's numerical flux is:

$$\begin{aligned} \mathbf{F}_{1/2}(\mathbf{U}_L, \mathbf{U}_R) &= \frac{1}{2} [\mathbf{F}(\mathbf{U}_L) + \mathbf{F}(\mathbf{U}_R) - |\tilde{\mathbf{A}}| (\mathbf{U}_R - \mathbf{U}_L)] \\ &= \frac{1}{2} [\mathbf{F}(\mathbf{U}_L) + \mathbf{F}(\mathbf{U}_R) - |u^*| (\mathbf{U}_R - \mathbf{U}_L)] \\ &= u^* \mathbf{U}_{L/R} + \begin{pmatrix} 0 \\ p^* \\ u^* p^* \end{pmatrix} \end{aligned} \quad (176)$$

Here the relevant velocity for upwinding is u^* , so

$$\mathbf{U}_{L/R} = \begin{cases} \mathbf{U}_L & \text{if } u^* \geq 0; \\ \mathbf{U}_R & \text{if } u^* < 0. \end{cases} \quad (177)$$

and by substitution into the discretized equations, we have:

$$\frac{\partial \mathbf{U}}{\partial t} + \mathbf{F}_{j+1/2}(\mathbf{U}_j, \mathbf{U}_{j+1}) - \mathbf{F}_{j-1/2}(\mathbf{U}_{j-1}, \mathbf{U}_j) = 0$$

(178)

or

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{1}{\Delta x} [(u^* \mathbf{U})_j - (u^* \mathbf{U})_{j-1}] = 0$$

We can see that when $\frac{u^* \Delta t}{\Delta x} = 1$, Roe's scheme is able to capture the contact continuity exactly. On the other hand, for van Leer's scheme, [\(175\)](#), we get:

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{1}{\Delta x} [(a \mathcal{M}_{(2)}^- \Phi)_{j+1} - (a (\mathcal{M}_{(2)}^+ - \mathcal{M}_{(2)}^-) \Phi)_j + (a \mathcal{M}_{(2)}^+ \Phi)_{j-1}] = 0 \quad (179)$$

and it is quite clear that when $|M_{j+1}| < 1$ we have $\mathcal{M}_{(2)}^- \neq 0$, and a flux representing down-wind properties enters the calculation – destroying upwinding and leading to false updating in the presence of stationary or moving contact discontinuities.

10.3 Advection Upstream Splitting

As we have seen above the basic ideas of Roe and van Leer have much to complement each other relative to mutual shortcomings in addressing the Riemann problem (and thereby the implementation of the Godunov idea). In the Advection Upstream Splitting Method (AUSM) (Liou and Steffen 1993; Liou 1996) a synthesis (of these two approaches) is made that retains the positive attributes while canceling the negative ones. The bases are to recognize and observe the physical correctness of the pressure-convection separating of van Leer [\(175\)](#). As we will see ([10.3.1 Sect. 11](#)) this is a crucial point in the implementation of the method to the effective field model of two-phase flow. Moreover, on this basis, it retains the advantages of bypassing the need for an eigensystem. This, besides efficiency in computation offers the means to addressing complex equations of state as well as problems that may be mildly non-hyperbolic – as is the

case in certain regions of the (relative) Mach number space in the multiphase flow model recommended and utilized herein. On the other hand, the method needs to incorporate the means of resolving the contact discontinuity issue explained above.

Recalling the convective component of (175):

$$\mathbf{f}^{(c)} = a_L \mathcal{M}_{(2)}^+(M_L) \Phi_L + a_R \mathcal{M}_{(2)}^-(M_R) \Phi_R \quad (180)$$

and that the contact discontinuity issue arises from using two separate convective speeds, here we use only one convective speed comprising contributions from both “ L ” and “ R ” states and write instead:

$$\mathbf{f}^{(c)} = u_{1/2} \Phi_{L/R} = a_{1/2} M_{1/2} \Phi_{L/R} \quad (181)$$

where $M_{1/2}$ is split according to van Leer:

$$M_{1/2} = \mathcal{M}^+(M_L) + \mathcal{M}^-(M_R) \quad (182)$$

and the sound speed $a_{1/2}$ is designed to satisfy certain discontinuity capturing properties as explained further below. It turns out that this has Roe’s (FDS) contact capturing quality we were also aiming for. The pressure splitting of (175) is maintained and likewise for the energy equation we use the total enthalpy H , while the interpolations involved are extended to still higher order.

We thus have the AUSM⁺ (Liou 1996) as:

$$\mathbf{F}_{1/2} = a_{1/2} M_{1/2} \Phi_{L/R} + \begin{pmatrix} 0 \\ p_{1/2} \\ 0 \end{pmatrix} \quad (183)$$

where $M_{1/2}$ and $p_{1/2}$ are defined as:

$$M_{1/2} \equiv \mathcal{M}_{(4)}^+(M_L) + \mathcal{M}_{(4)}^-(M_R), \quad M_{L/R} = u_{L/R}/a_{1/2} \quad (184)$$

$$p_{1/2} \equiv \mathcal{P}_{(5)}^+(M_L) p_L + \mathcal{P}_{(5)}^-(M_R) p_R \quad (185)$$

With

$$\mathcal{M}_{(4)}^\pm(M) = \begin{cases} \frac{1}{2} (M \pm |M|) & \text{if } |M| \geq 1, \\ \pm \frac{1}{2} (M \pm 1)^2 \pm \frac{1}{8} (M^2 - 1)^2 & \text{Otherwise.} \end{cases} \quad (186)$$

and

$$\mathcal{P}_{(5)}^\pm(M) = \begin{cases} \frac{1}{2} \left(1 \pm \frac{|M|}{M} \right) & \text{if } |M| \geq 1, \\ \frac{1}{4} (M \pm 1)^2 (2 \mp M) \pm \frac{3}{16} M (M^2 - 1)^2 & \text{Otherwise.} \end{cases} \quad (187)$$

The $a_{1/2}$ is a “numerical” speed of sound, and its specification is done so as to assure that a stationary shock is captured by satisfying the Rankine-Hugoniot condition exactly. Once the

average state has been so fixed there is no more control; we will use this result even for moving shocks as experience shows that performance is still very good. Consider the two fluid states $\mathbf{U}_L$ and $\mathbf{U}_R$ separated by a stationary shock and such that $u_L > u_R > 0$. According to Rankine-Hugoniot condition, numerical fluxes $\mathbf{F}_{1/2}$ must satisfy $\mathbf{F}_L = \mathbf{F}_{1/2} = \mathbf{F}_R$, which with the incorporation of the above convection specification yields:

$$\mathbf{F}_L = \begin{pmatrix} \rho_L u_L \\ \rho_L u_L^2 + p_L \\ \rho_L u_L H_L \end{pmatrix} = \begin{pmatrix} u_{1/2} \rho_L \\ u_{1/2} \rho_L u_L + p_{1/2} \\ u_{1/2} \rho_L H_L \end{pmatrix} = \mathbf{F}_{1/2} \quad (188)$$

Now from (186), if $M_L = \frac{u_L}{a_{1/2}} > 1$, we get $\mathcal{M}_{(4)}^+(M_L) = M_L$ and

$$\begin{aligned} u_{1/2} &= a_{1/2} \left(M_L - \frac{1}{2}(M_R - 1)^2 - \frac{1}{8}(M_R^2 - 1)^2 \right) \\ &= u_L - (u_R - a_{1/2}) \left(\frac{1}{2}(M_R - 1) + \frac{1}{8}(M_R + 1)^2 \right) \end{aligned} \quad (189)$$

Thus we can choose $a_{1/2} = u_R$, and it follows $u_{1/2} = u_L$, which leads to $p_{1/2} = p_L$ and, hence, satisfy the Rankine-Hugoniot condition.

The sound speed can be written in a more general form, which involves only “upwinding” states. From Prandtl’s relation across a stationary shock wave, we have

$$(a^*)^2 = (a_R^*)^2 = u_L u_R, \quad (190)$$

Thus we get

$$a_{1/2} = \frac{(a_L^*)^2}{u_L} \quad (191)$$

where a^* is the critical (sonic point) speed of sound. For ideal gas, it is expressed as:

$$(a^*)^2 = \frac{2(\gamma - 1)}{\gamma + 1} H \quad (192)$$

By extending the above analysis to cover other conditions, as $u_R < -a_R$ or in subsonic flows, we have:

$$a_{1/2} = \min(\tilde{a}_L, \tilde{a}_R) \quad \text{with} \quad \tilde{a} = \frac{(a^*)^2}{\max(a^*, |u|)} \quad (193)$$

By virtue of its derivation, (193) is only applicable to the capturing stationary shocks – it does not satisfy the Rankine-Hugoniot across a moving shock exactly. Still, based on a wide range of numerical tests we can state that this drawback is only in effecting a slight amount of numerical dissipation resulting only to a minimal smearing of the shock. In fact, even the rather simple choice

$$a_{1/2} = \frac{1}{2}(a_L + a_R) \quad (194)$$

is quite satisfactory, again at the cost of smearing in the shock profile. In all cases both amplitudes and positions are captured accurately, a manifestation of satisfying conservation properties.

In a further development, the AUSM⁺ scheme was extended to addressing all-speed situations (Liou 2006). This is done by adding properly-scaled dissipation terms to the convection and pressure fluxes to enhance the coupling between pressure and velocity fields, which is especially important for multiphase flow (Chang and Liou 2003, 2007) as we may be facing great disparities in fluid properties and flow speeds. The AUSM⁺-up scheme is written as

$$\mathbf{F}_{1/2} = \left(a_{1/2} M_{1/2} \rho_{L/R} + D^{(p)} \right) \mathbf{\Psi}_{L/R} + \begin{pmatrix} 0 \\ p_{1/2} + D^{(u)} \\ 0 \end{pmatrix} \quad (195)$$

With

$$\mathbf{\Psi} = (1, u, H)^T \quad (196)$$

$$D^{(p)} = \kappa_p \frac{\Delta M \max(1 - \bar{M}^2, 0) (p_L - p_R)}{\bar{a}} \quad (197)$$

$$D^{(u)} = \kappa_u \mathcal{P}_{(5)}^+(\bar{M}) \mathcal{P}_{(5)}^-(\bar{M}) \bar{\rho} \bar{a} (u_L - u_R) \quad (198)$$

And

$$\Delta M = \mathcal{M}_{(4)}^+(\bar{M}_L) - \mathcal{M}_{(1)}^+(\bar{M}_L) - \mathcal{M}_{(4)}^-(\bar{M}_R) + \mathcal{M}_{(1)}^-(\bar{M}_R) \quad (199)$$

The parameters $\bar{\rho}$, $\bar{a}$, and $\bar{M}$ are obtained as the arithmetic means of “L” and “R” states, and usually the coefficients $\kappa_p = \kappa_u = 1$ are sufficient to suppress numerical oscillation in both the gas and liquid fields.

Remarks on Performance

1. Discontinuity Capturing. This of course is the most crucial issue in respect to robustness as well as accuracy. For both contacts and shocks the greatest the jumps in flow and state variables involved the greatest the “stress” in the numerical scheme. Another stress is due to unsteady/nonstationary discontinuities, and unfortunately, theoretical results are available only for the stationary case: one is looking for sharp (nondiffusive) capturing. While this provides some sense of what could be expected in general for unsteady cases, as for example the development of a shock wave in an explosion (e.g., starting with ignition and run up to detonation), much of the performance characterization has to rely on empirical evidence; namely analysis of actual calculations and comparison to known solutions (like the Chapman-Jouget self-similar limit in 1D detonations) and/or experiments. On **stationary discontinuities** the situation can be summarized as follows:

- For a contact AUSM⁺ automatically captures exactly the discontinuity since the mass flux is zero. In other words $\rho u = 0$, $M_L = M_R = 0$, $p_L = p_R$. As shown already the FDS also satisfies this requirement, while the FVS fails it.
- For a stationary shock, AUSM⁺ with the choice of numerical speed of sound in (193) captures the discontinuity exactly (Liou 1996). Due to the design for possessing the Rankine-Hugoniot property, AUSM⁺, like Roe, cannot distinguish whether the discontinuity is a shock or an expansion – this can be remedied (Liou 2006) by the following redefinitions in (193):

$$\bar{a}_L = a^{*2} / \max(a^*, u_L), \quad \bar{a}_R = a^{*2} / \max(a^*, -u_R). \quad (200)$$

Figure 7

Supersonic flow past a sudden expansion (corner). The Roe method with entropy fix produces instability. The AUSM⁺ calculation (CFL=0.4 on a 400 x 400 grid) employed a MUSCL-type linear interpolation of primitive variables along with the van Albada limiter (van Albada et al. 1982) to control monotonicity

In Sect. 12, and in more detail in the Appendix, we illustrate these trends also for the case of multiphase flow, and also for the case of nonstationary discontinuities.

2. Positivity Preserving. Sudden expansions can lead to negative values of certain variables such as pressure, density, or volume fraction, which would terminate the calculation, thus, positivity preserving is an essential attribute of robustness of a numerical scheme. In an 1D situation violation of positivity can arise in the case of a Riemann problem with the two states set to move in opposite directions with velocities that exceed some critical value. In 2D the same can arise in a supersonic flow moving past a sharp, 90° expansion (corner) as illustrated in Fig. 7. In contrast to documented failings of several prominent flux schemes (Einfeldt 1991), AUSM⁺ exhibits a robust shock capturing capability typical of what is seen in Fig. 7. As another example, for the 1D Riemann problem $\{(-u, p, \rho)_L; (u, p, \rho)_R\}$ it has been shown (Liou and Edwards 1999) that AUSM⁺ guarantees positivity as long as: $u^{\Delta t}/\Delta x < 1$ and $u^{\Delta t}/\Delta x < 1/\gamma$ for pressure and density, respectively. For the linear case this condition coincides with the total variation diminish (TVD) condition of Harten (1983).

3. Transverse Shock Instability (Carbuncle Phenomenon). This sort of problem can arise in multidimensional situations, such as the one illustrated in Fig. 8, and it is due to spurious transverse waves that can amplify to a point that destroy the calculation. More specifically it has been suggested (Wada and Liou 1997) that this transverse action is originated by the few (unphysical) intermediate points of the profile approximating the shock, and their lateral influences, which in turn affect the shock in a multidimensional manner. A “shock fix” has been proposed, and it is effective but at the additional complication of the “if-then” check involved.

■ Figure 8

Density contours in steady supersonic flow past a blunt body positioned at right angles. Inset profiles are along the stagnation streamlines

As in the case for Roe (1981) (shown) also the Osher and Solomon (1982) method, as do most others fail. On the other hand, as is the case of $AUSM^+$ (shown) so is the van Leer VFS scheme not subject to this deficiency.

4. Efficiency, Generality. Unlike Roe's FDS, the numerical dissipation in $AUSM^+$ is merely a scalar, not of matrix type. As a result, the system is decoupled and hence requires only $\mathcal{O}(n)$ operations, n being the number of unknowns (and equations). Moreover, the same formula is easily extendable to include other conservation laws, or to fluids with general EOS, as is the case in multiphase flow. As in van Leer's FVS, the $AUSM^+$ does not require differentiation, or the flux Jacobian matrix; and the flux splitting always involves only the common mass-flux term for any additional conservation laws.

11 Advection Upstream Splitting for the Effective Field Model

11.1 Recasting the System of Equations in Quasi-Conservative Form

As made clear in the previous section, we need to begin the task of extending $AUSM$ to the effective field model by recasting the system of equations, (135)-(140), in conservation form. Unfortunately, this cannot be done in a complete manner – terms like $p\nabla\alpha$ and other similar terms remain, and as we shall see shortly these “nonconservative” terms create a new type of numerical challenge of significant proportions. The recasting then also aims to consolidate and

simplify these terms to the extent possible. The result is:

$$\frac{\partial}{\partial t}(\alpha_c \rho_c) + \nabla \cdot (\alpha_c \rho_c \mathbf{u}_c) = 0 \quad (201)$$

$$\frac{\partial}{\partial t}(\alpha_d \rho_d) + \nabla \cdot (\alpha_d \rho_d \mathbf{u}_d) = 0 \quad (202)$$

$$\frac{\partial}{\partial t}(\alpha_c \rho_c \mathbf{u}_c) + \nabla \cdot [\alpha_c (\rho_c \mathbf{u}_c \otimes \mathbf{u}_c + p_c \mathbf{I} + \rho_c E \mathbf{w} \otimes \mathbf{w})] = p_d \nabla \alpha_c + \Phi^K \quad (203)$$

$$\frac{\partial}{\partial t}(\alpha_d \rho_d \mathbf{u}_d) + \nabla \cdot [\alpha_d (\rho_d \mathbf{u}_d \otimes \mathbf{u}_d + p_d \mathbf{I})] = p_d \nabla \alpha_d - \Phi^K \quad (204)$$

$$\frac{\partial}{\partial t}(\alpha_c \rho_c E_c) + p_d \frac{\partial \alpha_c}{\partial t} + \nabla \cdot [\alpha_c (\rho_c E_c \mathbf{u}_c + p_c \mathbf{u}_c + \rho_c E (\mathbf{u}_d \cdot \mathbf{w}) \mathbf{w})] = \mathbf{u}_d \cdot \Phi^K \quad (205)$$

$$\frac{\partial}{\partial t}(\alpha_d \rho_d E_d) + p_d \frac{\partial \alpha_d}{\partial t} + \nabla \cdot [\alpha_d (\rho_d E_d \mathbf{u}_d + p_d \mathbf{u}_d)] = -\mathbf{u}_d \cdot \Phi^K \quad (206)$$

with $\mathbf{w} = \mathbf{u}_d - \mathbf{u}_c$ and $\Phi^K = \frac{\partial \mathbf{J}}{\partial t} + \nabla \cdot (\mathbf{u}_d \otimes \mathbf{J}) + (\mathbf{J} \cdot \nabla) \mathbf{u}_d + \mathbf{J} \times (\nabla \times \mathbf{u}_d)$.

Note: In one-dimensional flow the last term of Φ^K is identically zero, while in general it is convenient to combine the last two terms and use as:

$$\begin{aligned} & (\mathbf{J} \cdot \nabla) \mathbf{u}_d + \mathbf{J} \times (\nabla \times \mathbf{u}_d) \\ &= \alpha_c \rho_c E(\alpha_d) \left((u_d - u_c) \frac{\partial u_d}{\partial x} + (v_d - v_c) \frac{\partial v_d}{\partial x} + (w_d - w_c) \frac{\partial w_d}{\partial x} \right) \bar{\mathbf{e}}_1 \\ &+ \alpha_c \rho_c E(\alpha_d) \left((u_d - u_c) \frac{\partial u_d}{\partial y} + (v_d - v_c) \frac{\partial v_d}{\partial y} + (w_d - w_c) \frac{\partial w_d}{\partial y} \right) \bar{\mathbf{e}}_2 \\ &+ \alpha_c \rho_c E(\alpha_d) \left((u_d - u_c) \frac{\partial u_d}{\partial z} + (v_d - v_c) \frac{\partial v_d}{\partial z} + (w_d - w_c) \frac{\partial w_d}{\partial z} \right) \bar{\mathbf{e}}_3 \end{aligned} \quad (207)$$

We will demonstrate the numerics in one space dimension, and based on the above our system is:

$$\frac{\partial}{\partial t}(\alpha_c \rho_c) + \frac{\partial}{\partial x}(\alpha_c \rho_c u_c) = 0 \quad (208)$$

$$\frac{\partial}{\partial t}(\alpha_d \rho_d) + \frac{\partial}{\partial x}(\alpha_d \rho_d u_d) = 0 \quad (209)$$

$$\begin{aligned} & \frac{\partial}{\partial t}(\alpha_c \rho_c (1 + E(\alpha_d)) u_c) - \frac{\partial}{\partial t}(\alpha_c \rho_c E(\alpha_d) u_d) + \frac{\partial}{\partial x}(\alpha_c \rho_c u_c^2) \\ &+ \frac{\partial}{\partial x}[\alpha_c (p_c + \rho_c E(\alpha_d) (u_d - u_c)^2)] = p_d \frac{\partial \alpha_c}{\partial x} + \frac{\partial}{\partial x}(\alpha_c \rho_c E(\alpha_d) u_d (u_d - u_c)) + J \frac{\partial u_d}{\partial x} \end{aligned} \quad (210)$$

$$\begin{aligned} & - \frac{\partial}{\partial t}(\alpha_c \rho_c E(\alpha_d) u_c) + \frac{\partial}{\partial t}((\alpha_d \rho_d + \alpha_c \rho_c E(\alpha_d)) u_d) + \frac{\partial}{\partial x}(\alpha_d \rho_d u_d^2) \\ &+ \frac{\partial}{\partial x}(\alpha_d p_d) = -p_d \frac{\partial \alpha_c}{\partial x} - \frac{\partial}{\partial x}(\alpha_c \rho_c E(\alpha_d) u_d (u_d - u_c)) - J \frac{\partial u_d}{\partial x} \end{aligned} \quad (211)$$

$$\frac{\partial}{\partial t}(\alpha_c \rho_c E_c) + p_d \frac{\partial \alpha_c}{\partial t} + \frac{\partial}{\partial x}[\alpha_c (\rho_c H_c u_c + \rho_c E(\alpha_d) u_d (u_d - u_c)^2)] = u_d \Phi^K \quad (212)$$

$$\frac{\partial}{\partial t}(\alpha_d \rho_d E_d) + p_d \frac{\partial \alpha_d}{\partial t} + \frac{\partial}{\partial x}[\alpha_d \rho_d H_d u_d] = -u_d \Phi^K \quad (213)$$

With

$$H_d = E_d + \frac{p_d}{\rho_d} = e_d + \frac{1}{2}u_d^2 + \frac{p_d}{\rho_d}; \quad H_c = E_c + \frac{p_c}{\rho_c} = e_c + \frac{1}{2}u_c^2 + \frac{1}{2}E(\alpha_d)(u_d - u_c)^2 + \frac{p_c}{\rho_c};$$

$$\Phi^K = \frac{\partial J}{\partial t} + \frac{\partial}{\partial x}(u_d J) + J \frac{\partial u_d}{\partial x}$$

In final vector form with the convection terms collected in the manner suggested by AUSM is:

$$\frac{\partial \tilde{\mathbf{Q}}}{\partial t} + p_d \frac{\partial \mathbf{T}}{\partial t} + \frac{\partial}{\partial x}(\mathbf{F}^{(u_c)}) + \frac{\partial}{\partial x}(\mathbf{F}^{(u_d)}) + \frac{\partial}{\partial x}(\mathbf{F}^{(p)}) = p_d \frac{\partial \mathbf{G}}{\partial x} + \frac{\partial \mathbf{H}}{\partial x} + \mathbf{S} \quad (214)$$

Where:

$$\tilde{\mathbf{Q}} = \begin{pmatrix} \alpha_c \rho_c \\ \alpha_d \rho_d \\ \alpha_c \rho_c (1 + E(\alpha_d)) u_c - \alpha_c \rho_c E(\alpha_d) u_d \\ -\alpha_c \rho_c E(\alpha_d) u_c + (\alpha_d \rho_d + \alpha_c \rho_c E(\alpha_d)) u_d \\ \alpha_c \rho_c E_c \\ \alpha_d \rho_d E_d \end{pmatrix}; \mathbf{T} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \alpha_c \\ \alpha_d \end{pmatrix} \quad (215)$$

$$\mathbf{F}^{(u_c)} = \begin{pmatrix} \alpha_c \rho_c u_c \\ 0 \\ \alpha_c \rho_c u_c^2 \\ 0 \\ \alpha_c \rho_c H_c u_c \\ 0 \end{pmatrix}; \mathbf{F}^{(u_d)} = \begin{pmatrix} 0 \\ \alpha_d \rho_d u_d \\ 0 \\ \alpha_d \rho_d u_d^2 \\ \alpha_c \rho_c E(\alpha_d) (u_c - u_d)^2 u_d \\ \alpha_d \rho_d H_d u_d \end{pmatrix}; \quad (216)$$

$$\mathbf{F}^{(p)} = \begin{pmatrix} 0 \\ 0 \\ \alpha_c (p_c + \rho_c E(\alpha_d) (u_d - u_c)^2) \\ \alpha_d p_d \\ 0 \\ 0 \end{pmatrix}; \mathbf{G} = \begin{pmatrix} 0 \\ 0 \\ \alpha_c \\ \alpha_d \\ 0 \\ 0 \end{pmatrix}, \quad (217)$$

$$\mathbf{H} = \begin{pmatrix} 0 \\ 0 \\ \alpha_c \rho_c E(\alpha_d) u_d (u_d - u_c) \\ -\alpha_c \rho_c E(\alpha_d) u_d (u_d - u_c) \\ 0 \\ 0 \end{pmatrix}; \mathbf{S} = \begin{pmatrix} 0 \\ 0 \\ J \frac{\partial u_d}{\partial x} \\ -J \frac{\partial u_d}{\partial x} \\ u_d \Phi^K \\ -u_d \Phi^K \end{pmatrix}. \quad (218)$$

Note that the term due to velocity fluctuations in the continuous phase momentum equation is interpreted as a pressure modifier and it is split accordingly (along with pressure, rather than being treated together with the convection terms). In 2D or 3D this dyadic will have off-diagonal terms, and these interpreted as “stress” could be treated by simple central difference, or could be split as pressure.

11.2 Numerical Discretization

The convection and pressure splitting carry over directly from [10.3](#), and for the case that the volume fractions are basically continuous we have:

$$\begin{aligned} & \frac{1}{\Delta t} (\tilde{\mathbf{q}}_j^{n+1} - \tilde{\mathbf{q}}_j^n) + \frac{(p_d)_j^n}{\Delta t} (\mathbf{t}_j^{n+1} - \mathbf{t}_j^n) + \frac{1}{\Delta x} \left[\left(\mathbf{f}_{j+1/2}^{(u_c)} \right)^n - \left(\mathbf{f}_{j-1/2}^{(u_c)} \right)^n \right] \\ & + \frac{1}{\Delta x} \left[\left(\mathbf{f}_{j+1/2}^{(u_d)} \right)^n - \left(\mathbf{f}_{j-1/2}^{(u_d)} \right)^n \right] + \frac{1}{\Delta x} \left[\left(\mathbf{f}_{j+1/2}^{(p)} \right)^n - \left(\mathbf{f}_{j-1/2}^{(p)} \right)^n \right] \\ & = \frac{(p_d)_j^n}{\Delta x} [\mathbf{g}_{j+1/2}^n - \mathbf{g}_{j-1/2}^n] + \frac{1}{\Delta x} [\mathbf{h}_{j+1/2}^n - \mathbf{h}_{j-1/2}^n] + \mathbf{s}^* \end{aligned} \quad (219)$$

$$\mathbf{f}_{1/2}^{(u_c)} = \left[a_{1/2}(M_c)_{1/2}(\rho_c)_{L/R} + D_c^{(p)} \right] \begin{pmatrix} \alpha_c \\ 0 \\ \alpha_c u_c \\ 0 \\ \alpha_c H_c \\ 0 \end{pmatrix}_{L/R}; \quad (220)$$

$$\mathbf{f}_{1/2}^{(u_d)} = \left[a_{1/2}(M_d)_{1/2}(\rho_d)_{L/R} + D_d^{(p)} \right] \begin{pmatrix} 0 \\ \alpha_d \\ 0 \\ \alpha_d u_d \\ \alpha_c \left(\frac{\rho_c}{\rho_d} \right) E(\alpha_d) (u_c - u_d)^2 \\ \alpha_d H_d \end{pmatrix}_{L/R}; \quad (221)$$

$$\mathbf{f}_{1/2}^{(p)} = \begin{pmatrix} 0 \\ 0 \\ \alpha_c (p'_c)_{1/2} \\ \alpha_d (p'_d)_{1/2} \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ \alpha_c \left(\mathcal{P}_{(5)}^+(M_{c,L})p'_{c,L} + \mathcal{P}_{(5)}^-(M_{c,R})p'_{c,R} + D_c^{(u)} \right) \\ \alpha_d \left(\mathcal{P}_{(5)}^+(M_{c,L})p'_{d,L} + \mathcal{P}_{(5)}^-(M_{c,R})p'_{d,R} + D_d^{(u)} \right) \\ 0 \\ 0 \end{pmatrix}; \quad (222)$$

where the $(M_c)_{1/2}$ is also split to account for volume fraction variation across the cell interface:

$$\begin{aligned} (M_k)_{1/2} &= \frac{1}{(\alpha_k)_{\max}} \left[\max((\alpha_k)_L - (\alpha_k)_R, 0) (M_k)_L \right. \\ & \quad \left. + \max((\alpha_k)_R - (\alpha_k)_L, 0) (M_k)_R \right] \\ &+ \frac{(\alpha_k)_{\min}}{(\alpha_k)_{\max}} \left[\mathcal{M}_{(4)}^+((M_k)_L) + \mathcal{M}_{(4)}^-((M_k)_R) \right] \end{aligned} \quad (223)$$

with

$$\begin{aligned} (\alpha_k)_{\min} &= \min((\alpha_k)_L, (\alpha_k)_R) \\ (\alpha_k)_{\max} &= \max((\alpha_k)_L, (\alpha_k)_R) \end{aligned}$$

In the above

$$p'_c = p_c + \rho_c E(\alpha_d) (u_d - u_c)^2 \quad (224)$$

and the numerical dissipation terms $D_k^{(p)}, D_k^{(u)}$ are given in (197) and (198). For numerical speed of sound $a_{1/2}$, we employ the sound speed of the continuous phase. The same speed of sound is applied to both phases simultaneously.

For inter-phasic terms, we have:

$$\frac{(p_d)_j}{\Delta x} [\mathbf{g}_{j+1/2} - \mathbf{g}_{j-1/2}] = \frac{(p_d)_j}{\Delta x} \begin{pmatrix} 0 \\ 0 \\ ((\alpha_c)_{L,j+1/2} - (\alpha_c)_{R,j-1/2}) \\ -((\alpha_c)_{L,j+1/2} - (\alpha_c)_{R,j-1/2}) \\ 0 \\ 0 \end{pmatrix}; \quad (225)$$

$$\mathbf{h}_{1/2} = [a_{1/2}(M_d)_{1/2}] \begin{pmatrix} 0 \\ 0 \\ \alpha_c \rho_c E(\alpha_d) (u_d - u_c) \\ -\alpha_c \rho_c E(\alpha_d) (u_d - u_c) \\ 0 \\ 0 \end{pmatrix}_{L/R}; \quad (226)$$

$$\mathbf{s}^* = \begin{pmatrix} 0 \\ 0 \\ \frac{J_j}{\Delta x} \Delta_x (u_d) \\ -\frac{J_j}{\Delta x} \Delta_x (u_d) \\ (u_d)_j \Phi_j^K \\ -(u_d)_j \Phi_j^K \end{pmatrix} \quad \text{with } \Delta_x (\cdot) = \begin{cases} (\cdot)_j - (\cdot)_{j-1} & \text{if } J_j \geq 0; \\ (\cdot)_{j+1} - (\cdot)_j & \text{Otherwise.} \end{cases} \quad (227)$$

The forces expressed by the inter-phasic terms ($\mathbf{H}$ and $\mathbf{s}^*$) locally must cancel, and this is assured by discretizations (226) and (227).

As we have seen already above, with the AUSM numerical speed of sound, we should be able to handle shocks and expansion waves. However, in the presence of contact discontinuities, such as jumps in volume fractions, special consideration is needed. The issue arises because the discontinuity in α would cause the nonconservative terms in (203) and (204) to create nonphysical imbalances of pressure forces if discretization is done in the standard way of using common intermediate values of α_k and pressure at cell interface, and if the $\nabla \alpha_k$ term is discretized by central difference. The problem can be addressed by allowing the discontinuities to smear but this would defeat the purpose of a high-fidelity numerical scheme. Instead, we use (228) which with the help of  Fig. 9 can be seen to assure the balance of pressure force across each cell. Recall that by conservation treatment of convection terms, momentum fluxes are automatically balanced.

Figure 9

Illustration of pressure force applied on subcells of different fluids. (a) with continuous α_k ; (b) with noncontinuous α_k

$$\mathbf{f}_{j+1/2}^p = \begin{pmatrix} 0 \\ 0 \\ \delta_{c-c}(p_c)_{1/2} + \delta_{c-d}(p_d)_{1/2} \\ \delta_{d-d}(p_d)_{1/2} + \delta_{d-c}(p_d)_{1/2} \\ 0 \\ 0 \end{pmatrix}_{j+1/2} ; \quad (228)$$

$$\mathbf{f}_{j-1/2}^p = \begin{pmatrix} 0 \\ 0 \\ \delta_{c-c}(p_c)_{1/2} + \delta_{c-d}(p_d)_{1/2} \\ \delta_{d-d}(p_d)_{1/2} + \delta_{d-c}(p_d)_{1/2} \\ 0 \\ 0 \end{pmatrix}_{j-1/2}$$

δ_{c-c} , δ_{d-d} , δ_{c-d} , and δ_{d-c} are effective areas for fluid interface on cell boundary.

$$\delta_{c-c} = \min((\alpha_c)_L, (\alpha_c)_R) \quad (229)$$

$$\delta_{d-d} = \min((\alpha_d)_L, (\alpha_d)_R) \quad (230)$$

$$\delta_{c-d} = \max(0, \Delta\alpha_d) = \max(0, -\Delta\alpha_c) \quad (231)$$

$$\delta_{d-c} = \max(0, \Delta\alpha_c) = \max(0, -\Delta\alpha_d) \quad (232)$$

$$\Delta\alpha_k = (\alpha_k)_R - (\alpha_k)_L \quad (233)$$

In code implementation, we use a MUSCL type third-order scheme with Osher-Chakravarty TVD limiter (Chakravarty and Osher 1983) to determine fluid states on cell boundary. This allows us to sharply capture the shock wave and contact discontinuity while avoiding the numerical oscillation effectively.

11.3 Time Integration

For time integration, we use the Runge-Kutta time integration method (Jameson 1983). Supposing the system:

$$\frac{\partial \mathbf{Q}}{\partial t} + \mathbf{R}(\mathbf{Q}) = 0 \quad (234)$$

its time integration can be calculated by:

$$\begin{aligned} \mathbf{Q}^{(1)} &= \mathbf{Q}^n - \omega_1 \cdot \Delta t \cdot \mathbf{R}(\mathbf{Q}^n) \\ \mathbf{Q}^{(2)} &= \mathbf{Q}^n - \omega_2 \cdot \Delta t \cdot \mathbf{R}(\mathbf{Q}^{(1)}) \\ &\vdots \\ \mathbf{Q}^{(s-1)} &= \mathbf{Q}^n - \omega_{s-1} \cdot \Delta t \cdot \mathbf{R}(\mathbf{Q}^{(s-2)}) \\ \mathbf{Q}^{n+1} &= \mathbf{Q}^n - \omega_s \cdot \Delta t \cdot \mathbf{R}(\mathbf{Q}^{(s-1)}) \end{aligned} \quad (235)$$

For a four-stage Runge-Kutta, the coefficients are $(\omega_1, \omega_2, \omega_3, \omega_4) = (\frac{1}{4}, \frac{1}{3}, \frac{1}{2}, 1)$. Applying to our system of equations (214)-(218):

$$\frac{\partial}{\partial t} [\tilde{\mathbf{Q}}] + p_d [\mathbf{T}] + [\mathbf{R}] = 0 \quad (236)$$

we have:

$$\frac{1}{\Delta t} ([\tilde{\mathbf{Q}}]^{s+1} - [\tilde{\mathbf{Q}}]^n) + \frac{p_d}{\Delta t} \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \alpha_c^s - \alpha_c^n \\ \alpha_d^s - \alpha_d^n \end{pmatrix} + \omega_{s+1} [\mathbf{R}]^s = 0 \quad (237)$$

with

$$[\tilde{\mathbf{Q}}]^{s+1} + p_d^s \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \alpha_c^s \\ \alpha_d^s \end{pmatrix} = [\tilde{\mathbf{Q}}]^n + p_d^s \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \alpha_c^n \\ \alpha_d^n \end{pmatrix} - \omega_{s+1} \Delta t \begin{pmatrix} R_1^s \\ R_2^s \\ R_3^s \\ R_4^s \\ R_5^s \\ R_6^s \end{pmatrix} \equiv \begin{pmatrix} \tilde{W}_c \\ \tilde{W}_d \\ \tilde{M}_c \\ \tilde{M}_d \\ \tilde{E}_c \\ \tilde{E}_d \end{pmatrix} \quad (238)$$

Here $[\mathbf{R}]$ is the collection of all the spatial discretization and source terms. The specific implementation is as follows:

From the continuity equations we can update for the products $\alpha\rho$:

$$\alpha_c^{s+1} \rho_c^{s+1} = \alpha_c^n \rho_c^n - \bar{\omega}_{s+1} \Delta t R_1^s \equiv \tilde{W}_c \quad (239)$$

$$\alpha_d^{s+1} \rho_d^{s+1} = \alpha_d^n \rho_d^n - \bar{\omega}_{s+1} \Delta t R_2^s \equiv \tilde{W}_d \quad (240)$$

Then from the momentum equations we can update the velocities:

$$\begin{aligned} \alpha_c^{s+1} \rho_c^{s+1} (1 + E^s) u_c^{s+1} - \alpha_c^{s+1} \rho_c^{s+1} E^s u_d^{s+1} \\ = \alpha_c^n \rho_c^n (1 + E^n) u_c^n - \alpha_c^n \rho_c^n E^n u_d^n - \bar{\omega}_{s+1} \Delta t R_3^s \equiv \tilde{M}_c \end{aligned} \quad (241)$$

$$\begin{aligned} - \alpha_c^{s+1} \rho_c^{s+1} E^s u_c^{s+1} + (\alpha_d^{s+1} \rho_d^{s+1} + \alpha_c^{s+1} \rho_c^{s+1} E^s) u_d^{s+1} \\ = - \alpha_c^n \rho_c^n E^n u_c^n + (\alpha_d^n \rho_d^n + \alpha_c^n \rho_c^n E^n) u_d^n - \bar{\omega}_{s+1} \Delta t R_4^s \equiv \tilde{M}_d \end{aligned} \quad (242)$$

which provide the linear system:

$$\begin{pmatrix} \alpha_c^{s+1} \rho_c^{s+1} (1 + E^s) & -\alpha_c^{s+1} \rho_c^{s+1} E^s \\ -\alpha_c^{s+1} \rho_c^{s+1} E^s & \alpha_d^{s+1} \rho_d^{s+1} + \alpha_c^{s+1} \rho_c^{s+1} E^s \end{pmatrix} \begin{pmatrix} u_c^{s+1} \\ u_d^{s+1} \end{pmatrix} = \begin{pmatrix} \tilde{M}_c \\ \tilde{M}_d \end{pmatrix} \quad (243)$$

Note that instead of $E^s(\alpha_d^s)$, we could use $E^{s+1}(\alpha_d^{s+1})$ and obtain the solution by iteration.

To decode so as to obtain primitive variables (α, ρ, p) we need to involve the EOS and the energy equations.

$$\alpha_c^{s+1} \rho_c^{s+1} E_c^{s+1} + p_d^s \alpha_c^{s+1} = \alpha_c^n \rho_c^n E_c^n + p_d^s \alpha_c^n - \bar{\omega}_{s+1} \Delta t R_5^s = \tilde{E}_c \quad (244)$$

$$\alpha_d^{s+1} \rho_d^{s+1} E_d^{s+1} + p_d^s \alpha_d^{s+1} = \alpha_d^n \rho_d^n E_d^n + p_d^s \alpha_d^n - \bar{\omega}_{s+1} \Delta t R_6^s = \tilde{E}_d \quad (245)$$

We employ a stiffened gas EOS to relate internal energy (e) to the gas pressure and density:

$$e = (p_c + \gamma_c P_{\infty, c}) / \rho_c (\gamma_c - 1) \quad (246)$$

and the Newton iteration method to solve for ρ_c^{s+1} and α_c^{s+1} . To this end, the residuals Γ are:

$$\begin{aligned} \Gamma &= \begin{pmatrix} \Gamma_1 \\ \Gamma_2 \end{pmatrix} = \begin{pmatrix} \alpha_c^k \rho_c^k E_c^k + p_d^s \alpha_c^k - \tilde{E}_c \\ \alpha_d^k \rho_d^k E_d^k + p_d^s \alpha_d^k - \tilde{E}_d \end{pmatrix}; \Omega^k = \begin{pmatrix} p_c^k \\ \alpha_c^k \end{pmatrix} \\ \Gamma_1 &= \frac{\alpha_c^k}{\gamma_c - 1} (p_c^k + \gamma_c P_{\infty, c}) + \frac{1}{2} (\alpha_c^k \rho_c^k) ((u_c^{s+1})^2 + E(\alpha_d^k) (u_d^{s+1} - u_c^{s+1})^2) + p_d^s \alpha_c^k - \tilde{E}_c \\ \Gamma_2 &= \frac{\alpha_d^k}{\gamma_d - 1} (p_d^k + \gamma_d P_{\infty, d}) + \frac{1}{2} (\alpha_d^{s+1} \rho_d^{s+1}) (u_d^{s+1})^2 + p_d^s \alpha_d^k - \tilde{E}_d \\ &= \frac{\alpha_d^k}{\gamma_d - 1} \left(p_c^k - \frac{1}{2} (\alpha_c^{s+1} \rho_c^{s+1}) E'(\alpha_d^k) (u_d^{s+1} - u_c^{s+1})^2 + \gamma_d P_{\infty, d} \right) \\ &\quad + \frac{1}{2} (\alpha_d^{s+1} \rho_d^{s+1}) (u_d^{s+1})^2 + p_d^s \alpha_d^k - \tilde{E}_d \end{aligned}$$

where k is the index for iteration. The updated states after each iteration are

$$\Omega^{k+1} = \Omega^k - \left[\frac{\partial \Gamma}{\partial \Omega} \right]^{-1} [\Gamma] \quad (247)$$

With

$$\begin{aligned} \left[\frac{\partial \Gamma}{\partial \Omega} \right]_{11} &= \frac{\partial \Gamma_1}{\partial p_c^k} = \frac{\alpha_c^k}{\gamma_c - 1} \\ \left[\frac{\partial \Gamma}{\partial \Omega} \right]_{12} &= \frac{\partial \Gamma_1}{\partial \alpha_c^k} = \frac{p_c^k + \gamma_c P_{\infty,c}}{\gamma_c - 1} - \frac{1}{2} (\alpha_c^{s+1} \rho_c^{s+1}) E'(\alpha_d^k) (u_d - u_d)^2 + p_d^s \\ \left[\frac{\partial \Gamma}{\partial \Omega} \right]_{21} &= \frac{\partial \Gamma_2}{\partial p_c^k} = \frac{\alpha_d^k}{\gamma_d - 1} \\ \left[\frac{\partial \Gamma}{\partial \Omega} \right]_{22} &= \frac{\partial \Gamma_2}{\partial \alpha_c^k} = -\frac{p_d^k + \gamma_d P_{\infty,d}}{\gamma_d - 1} + \frac{\alpha_d^k}{2(\gamma_d - 1)} (\alpha_c^{s+1} \rho_c^{s+1}) E''(\alpha_d^k) (u_d - u_c)^2 - p_d^s \end{aligned}$$

At convergence, we have $p_c^{s+1} = p_c^k$ and $\alpha_c^{s+1} = \alpha_c^k$.

When the volume fraction of the disperse phase becomes vanishingly small (typically a value of 10^{-5} or 10^{-6}) rather than solving for it we take it at the specified limiting value and assume that it comes to instantaneous equilibrium with the continuous phase. The error associated with this treatment is negligibly small unless we try to resolve detailed motions of very dilute clouds, which then requires special treatment (► Sect. 12.5).

12 Numerical Testing in the ARMS Code

Computations were carried out with the computer code ARMS (All-Regime Multiphase Simulation) (Chang et al. 2009), and they were independently verified with the new code MuSiC-ARMS (Chang et al. 2010a). The original ARMS was built on a public-domain platform (SAMRAI, structured adaptive mesh refinement infrastructure), while MuSiC-ARMS is our own specialised tool based on irregular grids embedded in a multi-level Cartesian mesh. This same platform supports also the MuSiC-SIM code for compressible multi-hydrodynamics at the DNS level (sharp mobile interfaces coupling Navier-Stokes solvers for each phase) based on the sharp interface method (Nourgaliev et al. 2008; Chang et al. 2010b). An early task with this code will be to build the function $E(\alpha_d)$, as it appears in B-21 of Part I, from first principles.

In all computations presented here, continuous and disperse phase thermodynamics were modeled by ideal and stiffened (246) gas equations of state, respectively. The function $E(\alpha_d)$ was fitted with a fourth-order polynomial so that it reduces smoothly to zero rather than be

allowed to take on negative values when α_d exceeds the value that renders it zero:

$$E(\alpha_d) = \begin{cases} \frac{1}{2}\alpha_d [1 + 2C\alpha_d + 5C^2\alpha_d^2 + 8C^3\alpha_d^3 + 4C^4\alpha_d^4] & \text{if } (1 + C\alpha_d) \geq 0; \\ 0 & \text{Otherwise.} \end{cases} \quad (248)$$

All computations shown here were repeated with effective grid resolutions that spanned a factor of 8, typically 500 to 4,000 cells over a 10-m long computational domain. Unless otherwise noted the CFL number was set to 0.4. The base value of the parameter C in (248) was taken as -3.1 . Sample parametric calculations for values of 0 and -4.8 are also shown.

In these very basic series of tests we are concerned with the “bare” code: the inviscid constitutive treatment embodied in the EFM and computational performance of the numerical scheme to capture shocks and contact discontinuities sharply, stably, and without oscillations, even as numerical dissipation is severely reduced (grid refinement). The five series of computations and respective attributes of testing are as follows:

1. Uniformly-Translating Body-and-Fluid System. Ensuring that translation occurs without pressure disturbances, while maintaining any contact discontinuities present initially.
2. The Faucet Problem (Ransom 1987). Capturing the contact discontinuity of an abruptly initiated, at the inlet boundary of a computational domain, disperse stream that is subject to the acceleration of gravity.
3. Fitt’s Problem (1989). Capturing all wave forms and contacts in Riemann problems specified with initial discontinuities in Mach number and disperse phase volume fraction distributions. Test performance in relation to the hyperbolicity map of the EFM employed (Appendix B of Part I).
4. Shock Tube Problems. Capturing all wave forms and contacts in Riemann problems specified with initial discontinuities in pressure and disperse phase volume fraction distributions. Test performance in relation to the hyperbolicity map of the EFM employed (Appendix B of Part I). Test the role of drag to stabilize cases that are in the non-hyperbolic corridor.
5. Particle cloud dynamics in gaseous shocks. Capturing the acceleration and relaxation time of particles with and without drag. Compare to exact analytical results. Test performance in relation to the hyperbolicity map of the EFM employed (Appendix B of Part I). Test the role of drag to stabilize cases that are in the non-hyperbolic corridor.

As detailed below this initial, and far from comprehensive, testing shows sufficient promise to motivate continuing efforts in 2D and 3D geometries, and eventually quantitative comparisons with experimental data. It must be emphasized, however, that the use of function $E(\alpha_d)$ in compressible flows ($M \neq 0$) is strictly tentative until the kinds of extensions noted above have been completed.

12.1 Uniformly Translating Body-and-Fluid System

The ARMS solver is applied over a rectangular domain filled mostly with gas (liquid fraction 10^{-6}) and containing (a diffusely connected with its surroundings) circular liquid “blob” (gas

■ Figure 10

Snapshot of liquid “blob” motion in a uniformly convecting flow. Colors indicate disperse phase volume fractions. *Left: $t = 0.0$; Right: $t = 0.06$ s*

fraction 10^{-6}), all moving with the same velocity, which is maintained by a uniform/steady, diagonal (gas) inflow at the left and bottom boundaries, and a continuous outflow boundary condition at the other two boundaries of the domain. Obviously, there are no accelerations involved, and we expect that the solver will capture the interface without significant distortion due to motion, while the pressure remains smooth and uniform throughout within a very strict tolerance.

The computation shown in ● Fig. 10 is for a 10×10 m domain, the flow velocity vector has components of 100 m/s in each direction, and the code was programmed to refine the grid around the boundary by three levels of AMR with a refinement ratio of 2. Thus we have an effective field resolution of 400×400 grids. The pressure remained uniform throughout the computation to within 10^{-3} Pa, and the shape of the phase boundary remained without significant additional smearing.

12.2 The Faucet Problem

The ARMS solver is applied to compute the evolution of volume fraction distributions of a uniformly supplied disperse-phase stream ($\rho_d = 10^3 \text{ kg/m}^3$) at the top boundary of the computational domain as it accelerates under gravity. For the ideal problem, with no phase interactions, there is an exact analytical solution, a snapshot of which is shown in ● Fig. 11. Due to acceleration the disperse phase volume fraction decreases (that of the continuous phase increases) along the travel path. Also distinct is the sharp contact discontinuity formed by the sudden appearance of the inlet flow (at the “faucet”) upon initiation of the transient. The object

Figure 11
ARMS performance on the Faucet problem

of the computation is to capture the front stably, sharply, and without oscillations. It is known that non-hyperbolic formulations fail this task, unless they are gridded coarsely enough, which causes excessive smearing, and severe distortion of the waveform.

In [Fig. 11](#) we can see that with increasing resolution the computations converge to the exact discontinuous result, uniformly (around the front) and without oscillations.

12.3 Fitt's Problem

The ARMS solver is applied to a set of Riemann problems with discontinuity in Mach number designed to attain various “positions” in the hyperbolicity diagram ([Appendix B](#) of Part I) as shown in [Fig. 12](#). Each case is also considered with a discontinuity in disperse phase volume fraction (marked by superscript D). The specification of the various calculations performed, in terms of the $\{\alpha_d, p, u, T\}^L$ and $\{\alpha_d, p, u, T\}^R$ employed, is given in [Table D.1](#). The Mach number values are selected by specifying appropriate values of the gas temperatures (speeds of sound) as indicated in the table. As density of the disperse phase we use 10^4 kg/m^3 .

Fitt (1989) originally used this test problem to demonstrate the failure of numerical computations with an “ill-posed” EFM formulation, and we are not aware of any subsequent elaborations with other models.

All results obtained with ARMS are summarized in [Fig. D.1](#). We can see that all cases are stable, even those that are found inside the non-hyperbolic corridor. As noted in [Appendix](#)

■ Figure 12

Locations of the various Fitt's problem computational cases on the hyperbolicity map

B of Part I this is perhaps to be expected because of the “mild” non-hyperbolicity explained therein. Nevertheless, transonic conditions can become sensitive, as for example initially supersonic D cases that lead to transonic conditions due to wave reflections.

Characteristic velocities for the various waves can be obtained as illustrated in ► Fig. 13. The results are “paired” with those obtained from the hyperbolicity analysis (Appendix B of Part I) in ► Table 1. Note that the nomenclature (on the various λ s) in this table is not kept the same, and that a fourth eigenvalue is now present (u_c); this is due to inclusion of the energy equation in the computation. A couple of sample results illustrating grid convergence are shown in ► Fig. 14.

Finally, a number of parametrics on the value of C are shown in ► Fig. 15, along with their positions on the hyperbolicity map in ► Fig. 16. In addition to further supporting the conclusions reached above, these results also demonstrate that there is a considerable tolerance on the value of C .

12.4 Shock Tube Problems

The ARMS solver is applied to a series of Riemann problems with discontinuity in pressures and volume fractions of the disperse phase, whose density is taken as that of water. Two tests are with single phase, air or water, set at extremely high pressure ratio, and these are in excellent agreement with exact results. The rest of the cases involve two-phase conditions under varying pressure ratio so as to cover wide ranges on the hyperbolicity map as shown in ► Fig. 17. They

Figure 13

Propagation of characteristic waves in sample subsonic (*top*) and supersonic (*bottom*) cases. All these cases were run on 1,000 cells grid

are denoted as the S cases. All cases are specified in [Table D.2](#) in terms of the applicable $\{\alpha_d, p, u, T\}^L$ and $\{\alpha_d, p, u, T\}^R$. As indicated in the table each case was run both with a uniformly distributed disperse phase as well as with a jump at the location of the diaphragm. To maximize the computational challenge all cases were run with zero drag.

The results are summarized in Appendix, [Fig. D.2](#). We can see that instabilities develop (seen better yet in Mach number plots as in [Fig. 18](#)), however they can be effectively controlled by a small amount of dissipation, as is the case for the Cloud Dynamics problems discussed below.

12.5 Particle Cloud Dynamics in Gaseous Shocks

The ARMS solver is applied to a shock tube configuration driven by single-phase gas, and various kinds of particle clouds (water density, particle diameter 2 mm) in the expansion

■ Table 1

Comparison of the characteristic wave speeds from ARMS with those from the rule of thumb found in [Appendix B](#) of Part I. Of the two numerical entries the one on the *left* corresponds to the eigenvalues according to the rule developed in [Appendix B](#) of Part I, and the one on the *right* is the value found in the ARMS computation. The later case the speed of sound is found from the local computed temperature

Case	$\lambda_1; u_c + a_c$	$\lambda_2; u_c$	$\lambda_3; u_d$	$\lambda_4; u_c - a_c$
F_A^D (subsonic)	340.7; 337.1 1%	225.3; 199.2 13 %	64.7; 50 22 %	-277.3; -280.0 1 %
F_C^D (transonic)	439.0; 442.5 -1%	341.0; 301.9 11 %	69.0; 50 27 %	-150.0; -172.0 -15%
F_E^D (supersonic)	826.0; 781.7 5%	675.7; 497.1 26 %	46.3; 50 -8 %	260.0; 185.0 29%

■ Figure 14

Illustration of ARMS performance under grid refinement for Fitt's problem

section as specified in ➤ [Table D.3](#). To explore the effect of initial discontinuity each C case was run with a smooth (Gaussian) as well as with a top hat profile (subscripts S and T respectively). To explore the effect of drag to stabilize an unstable computation, each case was run with zero drag (subscript zero) as well as a constant drag coefficient of 0.41 (no subscript). However it should be noted that even one-tenth of this value is sufficient to stabilize these cases. Finally, to test against the exact result for a single particle accelerated in a shock, we have also case D (for dilute cloud) with particle density $\rho_d = 100 \text{ kg/m}^3$.

The positions of the various cases on the hyperbolicity map are indicated in ➤ [Fig. 19](#). The results are summarized in ➤ [Fig. D.3a](#) for the C cases and ➤ [Fig. D.3b](#) for the D case. A key

Figure 15

■ Figure 16

Locations of the various Fitt's problem C-parametrics on the hyperbolicity map. All cases are stable on 4000 cells grid

■ Figure 17

Ranges on the hyperbolicity map covered in each of the Shock tube problem computations

Figure 18

Illustrative snapshots of the shock tube problem computations showing stable calculations and cases with incipient instability

result is the recovery (Fig. 20) of the exact analytical result for displacement as a function of time:

$$x(t) = u_c t - \frac{4\rho_d d_d}{3\rho_c C_d} \ln \left(\frac{3\rho_c C_d u_c t}{4\rho_d d_d} + 1 \right) \quad (249)$$

Another key result is that normal drag cases are stable even though they encroach well into the non-hyperbolic zone. For those cases that are unstable the inception is around $M \sim 1$ a result already seen in the S cases above.

13 Conclusions and Outlook

In Part II, we have addressed computations in compressible multi-hydrodynamics with a heavy disperse phase (Piltch et al. 1996; Theofanous et al. 2006; Theofanous and Dinh 2008). Such flows are the counterpart of bubbly flows (found extensively in past work), and a necessary

Figure 19

Locations of the cloud dynamics problem computations on the hyperbolicity map

Figure 20

Recovery of exact analytical results for "single" particle displacement under a constant gas flow and drag coefficient (0.41)

complement in the understanding of disperse systems. The principal new ingredient is accessibility of high relative velocities. This is a consequence of large disperse-to-continuous density ratios, which yields strong inviscid interactions and associated inertia coupling effects. On the other hand, and in a broader context of applicability, we have also addressed high-fidelity capturing of shocks and contact discontinuities as pertinent to *ab initio* simulation of multiphase flow regimes and of steam explosion phenomena (Theofanous et al. 1998a,b, 1999; Yuen and Theofanous 1999).

We have shown that the EFM of Part I, with its essentially hyperbolic character as endowed by a closure that captures inviscid interactions, in combination with a numerical treatment that is based on the AUSM scheme, make available a framework for high-fidelity computation of shocks, expansion waves, and contact discontinuities in high-speed flows. In particular, by accounting for the fundamentally distinct physics between convective momentum transfer and pressure forces, we could deal with discretization of the terms that arise from inviscid interactions as well as of the nonconservative terms involving the volume fraction gradient. Inviscid computations applied to a series of highly sensitive test problems showed that stable solutions can be obtained with effectively unlimited grid resolution. Certain extreme cases, such as strong shock wave interacting with step change in disperse phase volume fraction can lead to mild instability, which however can be eliminated by a small amount of drag.

The pursuit of this framework to practical simulations, for example, shock-induced fluidization of particulated solid or liquid masses, requires developments in three main directions of further constitutive treatment. One would be toward an extension of the function $E(\alpha_d)$ into the Mach number space; that is, the definition of function $E(\alpha_d, M)$, while at the same time extending it to dense systems ($\alpha_d > 0.3$). The second direction would be toward accounting for mechanisms of direct particle to particle momentum transfers, such as pressure wave propagation via contacts in the fully packed regime, and collisions during the early stages of dispersal (dense regime). Some approach on this subject can be initially gained with reference to granular flows. The third direction, necessary for shock-induced fluidization of liquid masses, would require inclusion of the interfacial area transport, a modified version of (65) in Part I, supplemented by a constitutive treatment for interfacial breakup (and perhaps coalescence) appearing as a source term on the right-hand side. Alternatively, the numerical framework presented here could be adapted to accommodate multi-length scale particulate matter, each scale with own continuity and momentum equations, along with appropriate source/sink terms to account for breakup and coalescence phenomena. In all three directions well-instrumented experiments and direct numerical simulations will provide the building blocks for which the present foundation is beckoning.

Abstract: In practice, the results of experiments seldom coincide with the computational results obtained from the mathematical models of the respective experiments. Discrepancies between experimental and computational results stem from both experimental and computational uncertainties. Such discrepancies motivate the activities of model verification, validation, and predictive estimation. Following a brief review of the classification and origins of experimental uncertainties, this chapter presents widely used statistical and deterministic methods for computing response sensitivities to model parameters, highlighting, in particular, the novel *adjoint sensitivity analysis procedure* (ASAP) for augmented nonlinear large-scale systems with feedback. The practical use of ASAP is illustrated by a large-scale application for analyzing the dynamic reliability of an accelerator system design for the International Fusion Materials Irradiation Facility (IFMIF).

Response sensitivities to parameters and the corresponding uncertainties are the fundamental ingredients for *predictive estimation* (PE), which aims at providing a probabilistic description of possible future outcomes based on all recognized errors and uncertainties. The key PE-activity is *model calibration*, which uses *data adjustment* and *data assimilation* procedures for addressing the integration of experimental data for updating (calibrating or adjusting) parameters in the simulation model. This chapter also presents a state-of-the-art mathematical framework for time-dependent data assimilation and model calibration, using sensitivities and covariance matrices. The basic premise underlying this mathematical framework is that only means and covariance matrices are a priori available, which is the usual situation when analyzing large-scale systems. Under this premise, the maximum entropy principle of statistical mechanics is employed in conjunction with information theory to construct a Gaussian prior distribution that takes all of the available information into account while minimizing (in the sense of quadratic loss) the introduction of spurious information. This prior distribution also comprises correlations among model parameters and responses, thus generalizing the state-of-the-art data assimilation algorithms used in geosciences.

The posterior distribution for the best-estimate calibrated model parameters and responses is constructed by using Bayes' theorem. The best-estimate predicted mean values and reduced covariances, which are customarily needed when employing decision theory under "quadratic loss," are computed by extracting the bulk contributions via the saddle-point method. The minimum value of the quadratic form appearing in the exponent of the Gaussian posterior distribution can be used as an indicator of the agreement between the computed and experimentally measured responses. When all information is consistent, the posterior probability density function yields reduced best-estimate uncertainties for the best-estimate model parameters and responses. This fact is illustrated in this chapter for a time-dependent thermal-hydraulic system that can serve as a benchmark for validating and calibrating thermal-hydraulic codes. The novel features of the data assimilation and model calibration methodology presented in this chapter include: (1) treatment of systems involving correlated parameters and responses; (2) simultaneous calibration of all parameters and responses; and (3) simultaneous calibration over *all* time intervals; this includes the usual two-step time advancement procedures used in geophysical sciences.

Open issues (e.g., explicit treatment of modeling errors, reducing the computational burden, removing the current restriction to Gaussian distributions) are addressed in the concluding section of this chapter. Since predictive "best-estimate" numerical simulation models are essential for designing new technologies and facilities, particularly when the new systems cannot be readily tested experimentally, the only path to progress is to reduce drastically the uncertainties associated with such simulation tools while enlarging the respective validation domains.

1 Introduction

In practice, the results of experiments seldom coincide with the computational results obtained from the mathematical models of the respective experiments. Discrepancies between experimental and computational results are due to both experimental and computational uncertainties. The experimental uncertainties are traditionally classified as *random* and *systematic errors*; both types will be discussed in ► Sect. 2. Models of complex physical systems are usually subject to *stochastic uncertainties* and *subjective or epistemic uncertainties*. Stochastic uncertainties arise because the system under investigation can behave in many different ways. Subjective or epistemic uncertainties arise from the inability to specify an exact value for a parameter that is assumed to have a constant value in the respective investigation. Epistemic (or subjective) uncertainties characterize a degree of belief regarding the location of the appropriate value of each parameter. In turn, these subjective uncertainties lead to subjective uncertainties of the response, thus reflecting a corresponding degree of belief regarding the location of the appropriate response values as the outcome of analyzing the model under consideration. A typical example of a complex system that involves both stochastic and epistemic uncertainties is a nuclear reactor power plant: in a typical risk analysis of a nuclear power plant, stochastic uncertainty arises due to the *hypothetical* accident scenarios which are considered in the respective risk analysis, while epistemic uncertainties arise because of uncertain parameters that underlie the estimation of the probabilities and consequences of the respective hypothetical accident scenarios.

Discrepancies between experimental and computational results actually provide the basic motivation for performing quantitative model verification, validation, and predictive estimation. *Model verification* is the process of determining that a model implementation accurately represents the developer's conceptual description of the model and the solution to the model; loosely speaking, "verification" means "are you solving the mathematical model correctly?" Model verification comprises two major activities: (1) hierarchical *numerical algorithm verification* (NAV), including numerical error estimation and (2) *software quality assurance* (SQA). Software quality assurance includes static analysis and dynamic testing (including nonregression, black box, and glass box testing). NAV includes testing the respective algorithm against analytic and manufactured solutions, ODE and PDE benchmark solutions, symmetry and conservation tests, and iterative convergence tests. The goal of NAV is to determine the observed (demonstrated) order of accuracy of models, by using *a priori* and *a posteriori* methods (e.g., Richardson's extrapolation, adaptive grid refinement, grid convergence index). Often the observed accuracy is less than the formal accuracy of the respective numerical method, because of singularities, discontinuities, grid clustering, under-resolved grids, boundary condition effects, non-asymptotic convergence, inadequate iterations, coupling of numerical errors to appearance of new time- and spatial-scales, etc. The responsibility of NAV rests with the code development team.

Model validation is the process of determining the degree to which a model is an accurate representation of the real world from the perspective of the intended uses of the model. In short, "model validation" means "does the model represent reality?" Ideally, model validation involves comparing system responses from multiple realizations of an experiment or multiple experiments with computational results that are characterized by probability distributions. However, model validation needs to be performed not only when strong experimental evidence exists (e.g., in the form of confirmatory mockups) but also for novel designs, when only elementary

experimental evidence may be available. Verification and predictive validation must be based on a well-established set of scientific approaches that will allow the a priori announcement of computational uncertainties with a quantified level of confidence. Model verification and validation can be done only by selected benchmarking, while taking into account systematically, by using sensitivities, all of the uncertainties (computational, experimental, etc) affecting the respective model.

The goal of *predictive estimation* (PE) is to provide a probabilistic description of possible future outcomes based on all recognized errors and uncertainties. Predictive estimation comprises three key elements: model calibration, model extrapolation, and estimation of the validation domain. *Model calibration* addresses the integration of experimental data for the purpose of updating the data of the computer model. Model calibration commences with the identification and characterization of errors or uncertainties from all steps in the sequence of modeling and simulation processes needed for a computational model prediction. This includes (1) data error or uncertainty (input data such as cross sections, model parameters such as reaction-rate coefficients, initial conditions, boundary conditions, and forcing functions such as external loading), (2) numerical discretization error, and (3) uncertainty (e.g., lack of knowledge) in physics processes being modeled. Important components include the estimation of discrepancies in the data and, more importantly, estimation of the biases between model predictions and experimental data. The mathematical framework for model calibration is provided by the *data adjustment and data assimilation* procedures (see, e.g., Cacuci et al. 2010). The state of the art of calibration of models is fairly well developed, but current methods are still hampered in practice by the significant computational effort required, especially for computing sensitivities of responses to parameters in large-scale systems. Methods for reducing the computational effort are of great interest, and methods based on adjoint models (Cacuci 2003; Cacuci et al. 2005) show great promise in this regard.

Model extrapolation addresses the prediction uncertainty in new environments or conditions of interest, including both untested parts of the parameter space and higher levels of system complexity in the validation hierarchy. Extrapolation of models and the resulting increase of uncertainty are poorly understood, particularly the estimation of uncertainty that results from nonlinear coupling of two or more physical phenomena that were not coupled in the existing validation database.

The *estimation of the validation domain* of the physics underlying the models of interest requires estimation of contours of constant uncertainty in the high-dimensional space that characterizes the application of interest. In practice, this involves the identification of areas where the predictive estimation of uncertainty meets specified requirements for the performance, reliability, or safety of the system of interest. The state of the art in the estimation of the validation domain is still in an early stage in both the conceptual and mathematical development. For example, when coupled phenomena occur, in particular for safety analyses, validation is restricted to either mockup or component-level experimental comparison, with little predictive capability.

Developing predictive, experimentally validated, “best-estimate” numerical models is particularly important for designing new technologies and facilities based on novel processes while striving to avoid, as much as possible, the costly and lengthy procedures of building representative mock-up experiments which might confirm – but would not necessarily explain – the predictions of simulation tools. For example, the performance of fuels and materials, in particular fuel irradiation behavior, is dominated by the coupled effects of several phenomena. The

corresponding confirmatory mock-up experiments have traditionally been very expensive and time-consuming (e.g., multiyear irradiations), with little or no predictive capability; improvements in this regard carry a very high potential payoff. Systems-level analysis tools, for example, are used typically for predicting properties of systems to be constructed.

The essential roles played by sensitivities and uncertainties in quantifying the degree of reliability of predicted results can be readily illustrated by considering an example from the field of reactor physics. This field was arguably the first scientific field in which sensitivity and uncertainty analysis, followed by data assimilation and adjustment of parameters (cross sections), was initiated based on mathematically and physically well-founded systematic procedures for benchmarking both nuclear data libraries as well as the corresponding computations. Consider, as an example, the comparisons (Mosteller 2007) of experimental and computational results for several critical assemblies reproduced in the Table 1.

In Table 1, the names of the various assemblies are listed in the first column; the *experimentally measured* multiplication factors, k_{eE} , of the respective assemblies are listed in the second column; the *computed* multiplication factors, $(k_{eff})_c$, obtained by using the Monte Carlo Code MCNP are given in columns three, four, five, and six, corresponding, respectively, to the widely used cross section libraries ENDF/B-VII.0, ENDF/B-VI, JEFF-3.1, and JENDL-3.3.

To begin with, note that the experimental results of an experiment devised to measure a physical parameter x are reported in the form “ $x = \mu \pm \sigma$.” The computational results are listed in a similar form. The conventional interpretation of such statements is that “ μ is the most probable value of the parameter x ,” and “ σ is the standard deviation” characterizing the range of uncertainty for the true but unknown exact value of x . More precisely, the implication of the statement “ $x = \mu \pm \sigma$ ” is that, if the measurement of x were to be repeated (on the same experimental facility), the *a priori* probability of a result within the range dx at any value x would be given by the Gaussian (or normal) distribution

$$P(x) dx = \frac{1}{\sqrt{2\pi\sigma^2}} \exp \left[-1/2 \left(\frac{x - \mu}{\sigma} \right)^2 \right] dx. \quad (1)$$

■ Table 1

MCNP5 results for criticality safety validation set

It is important to note that even though the actual value of the physical parameter x is not known, that value is not random but fixed (at a definite but unknown value). To emphasize this fact, variables (such as x) associated with a distribution are commonly referred to as *variates*, rather than random variables. More formally, it may be argued that it is more sensible to consider the probabilities of the statement that *the value of x is μ* is correct for different values of μ . In practice, experimental facilities are never “ideal measuring instruments”; hence, when measurements are repeated, the resulting values are never absolutely identical. Rather, the measured values follow a pattern, that is, they manifest a distribution. Furthermore, most distributions arising in practice are sufficiently narrow to be approximated by a normal (Gaussian) distribution. Thus, any experimental facility designed to measure a parameter x may be considered to function as a generator of random numbers drawn from the normal distribution of mean μ and standard deviation σ . In this sense, it is justified to treat a possible result of a measurement as a random variable and the actual experimental data as a sample drawn from a distribution. Informally, standard deviations are often referred to as “uncertainties.” The meaning of statements about measurements and their properties (e.g., “accuracy,” “uncertainties”) will be discussed in ► Sect. 2, in the sequel.

If x is a variate, then $\delta x \equiv x - \mu$ is also a variate, with mean $\langle \delta x \rangle = 0$. The *variance* (the standard deviation squared) of x is, by definition, the mean of the square of δx , that is, $\text{var}(x) = \langle (\delta x)^2 \rangle$. The sum (and difference) $x = x_1 \pm x_2$ of two variates x_1 and x_2 is also a variate. Since $\delta x = \delta x_1 \pm \delta x_2$, it follows that

$$\text{var}(x) = \langle (\delta x_1 \pm \delta x_2)^2 \rangle = \langle (\delta x_1)^2 \rangle \pm 2 \langle \delta x_1 \delta x_2 \rangle + \langle (\delta x_2)^2 \rangle. \quad (2)$$

The cross term $\langle \delta x_1 \delta x_2 \rangle$ is called the *covariance* of x_1 and x_2 ; it vanishes if the variates x_1 and x_2 vary independently of each other. Note that the reciprocal statement (i.e., the statement “if $\text{cov}(x_1, x_2) = 0$ then x_1 and x_2 are independent of each other”) is not necessarily true. A note of caution: there is no generally accepted notation to distinguish between absolute and relative variances and covariances; therefore, the use of absolute or relative variances and covariances must be inferred from the context.

Comparing, for each assembly, the experimental results (shown in the first column of the above table) with the computational results indicates that they do not coincide; in most cases, both the respective “means” (also called “nominal values”) and uncertainties (i.e., standard deviations) quoted for the effective multiplication factors differ from the corresponding computational results. Moreover, the very small “uncertainties,” of the order of $O(10^{-4})$, quoted for the computational results seem to indicate that the computations are somehow *inconsistent* with the measurements. Is this truly the case?

The computed results represent the Monte Carlo solution of the steady-state neutron transport equation, which, for the purposes of this discussion, can be written in the form

$$\Omega \cdot \nabla \psi + \Sigma \psi = \frac{1}{k_{\text{eff}}} S_f [\psi] + S_s [\psi]. \quad (3)$$

In the above equation, ψ denotes the neutron angular flux; $\Omega \cdot \nabla \psi$ denotes the streaming operator accounting for the rate of change of the neutron angular flux along the streaming path in the direction of particle motion Ω ; the term $\Sigma \psi$ accounts for the rate at which neutrons are lost due to collisions of any kind with the nuclei comprising the medium; the term $S_s [\psi]$ denotes the “fission source” accounting for the rate at which neutrons are born in the

medium due to fissions; and the term $S_f[\psi]$ denotes the scattering source accounting for the rate at which neutrons are produced as a result of particle interactions with nuclei other than interactions leading to fissions. For the critical assemblies listed in the above table, the boundary conditions customarily used for the computation of the neutron angular flux ψ are the so-called “free-surface” or “vacuum” boundary conditions, which stipulate that neutrons leaving the external surface of the assembly will not reenter it. Although such boundary conditions represent a mathematical idealization, they are sufficiently representative of physical reality if the neutrons have a negligible probability of returning. Since both the neutron transport equation and the free-surface boundary conditions are homogeneous in ψ , it follows that (3) must be solved as an *eigenvalue problem* to determine the angular neutron flux ψ . For the specific form displayed in (3), the eigenvalue of the neutron transport equation is the so-called “effective neutron multiplication factor,” k_{eff} . “Criticality” is attained, by definition, when $k_{eff} = 1$, exactly.

Uncertainties in computational results arise from several distinct causes, most often stemming from:

1. The adequacy or inadequacy of the mathematical equations to model the actual phenomenon, which may give rise to modeling uncertainties;
2. The numerical methods used to solve the model's equation, which also give rise to modeling uncertainties;
3. The data and parameters in a model (e.g., cross sections), which give rise to parameter uncertainties.

Other sources of uncertainties may occur in nonlinear models, but these sources are not relevant to the present discussion, since the neutron transport equation is linear in the flux ψ . Since the neutron transport equation is known to model the physical phenomena occurring in the benchmark assemblies to an extremely high degree of accuracy (i.e., up to the omission of neutron–neutron collisions), it follows that the uncertainties in $(k_{eff})_c$ can only stem from the numerical method used to solve the transport equation and from uncertainties in the cross section that enter as parameters in the respective computation. In the present case, the geometrical modeling of the various assemblies is also extremely accurate, so uncertainties due to geometrical modeling can also be neglected.

To quantify the uncertainties that could stem from cross section uncertainties, it is convenient to rearrange (3) in the form

$$\Omega \cdot \nabla \psi + \Sigma \psi = \frac{1}{\gamma} \{S_s[\psi] + S_f[\psi]\}.$$

The eigenvalue γ of the above homogeneous equation can be written explicitly in the form $\gamma = c P(\Sigma R)$, where $P(\Sigma R)$ denotes the average next-collision probability, and

$$c \equiv \frac{\bar{\nu} \sigma_f + 2\sigma_{n,2n} + 3\sigma_{n,3n} + \cdots + \sigma_s}{\sigma_{tot}}, \quad (4)$$

where $\bar{\nu}$ denotes the average number of neutrons emitted per fission, σ_f denotes the fission cross section, σ_s denotes the scattering cross section, $\sigma_{n,2n}$, $\sigma_{n,3n}$, $\dots$ denote the neutron multiplication cross sections; σ_a denotes the absorption cross section; and $\sigma_{tot} = \sigma_a + \sigma_s + \sigma_f + \sigma_{n,2n} + \cdots$ denotes the total cross section. The order-of-magnitude uncertainties in c can be assessed, step by step, by commencing, for example, with the contribution from the fission neutrons, $\bar{\nu} \sigma_f$. As

(4) indicates, the relative uncertainty in c must be proportional to the relative uncertainty in the fission cross section, that is,

$$\frac{\delta c}{c} \sim \frac{\delta \sigma_f}{\sigma_f} \rightarrow \text{var}(c) \sim \text{var}(\sigma_f). \quad (5)$$

Examining various cross section libraries (e.g., ENDF/B-VII.0, ENDF/B-VI, JEFF-3.1, and JENDL-3.3, available from the OECD/NEA Data Bank) reveals that the relative standard deviation in the fission cross section of ^{235}U is of the order of 2%. This implies that $\delta c/c \sim \delta \sigma_f/\sigma_f \sim O(10^{-2})$.

The next step in this qualitative reasoning is to note that c is proportional not only to σ_f but also to $\bar{\nu}$; hence, a more accurate estimate of the relative uncertainty $\delta c/c$ is

$$\frac{\delta c}{c} \simeq \frac{\delta \bar{\nu}}{\bar{\nu}} + \frac{\delta \sigma_f}{\sigma_f} \rightarrow \text{var}(c) \simeq \text{var}(\bar{\nu}) + \text{var}(\sigma_f), \quad (6)$$

since σ_f and $\bar{\nu}$ are uncorrelated. Since the relative standard deviation in $\bar{\nu}$ for ^{235}U is ca. 6%, it follows that the relative standard deviation in c for GODIVA would be approximately $\sqrt{(0.02^2 + 0.06^2)} = 0.063$, which is greater than the uncertainty in either σ_f or $\bar{\nu}$. This result confirms the expectation that the more uncorrelated variates are considered as contributing to the final uncertainty in a result, the larger the resulting uncertainty in the respective result.

A further step for improving the estimation of the uncertainty in c can be taken by considering also the uncertainty in the absorption cross section. Ignoring (for simplicity) the relative uncertainties contributed by the other cross sections to the relative uncertainty in σ_t , it follows from (4) that

$$\frac{\delta c}{c} \simeq \frac{\delta \bar{\nu}}{\bar{\nu}} + \frac{\delta \sigma_f}{\sigma_f} - \frac{\delta \sigma_a}{\sigma_a}. \quad (7)$$

since σ_a and σ_f are correlated to each other but $\bar{\nu}$ is independent of the various cross sections, it follows from (7) that

$$\text{var}(c) \simeq \text{var}(\bar{\nu}) + \text{var}(\sigma_f) + \text{var}(\sigma_a) - 2 \text{cov}(\sigma_f, \sigma_a). \quad (8)$$

Neglecting, once again, the relative uncertainty in the capture cross section σ_c , one readily obtains the relations

$$\text{var}(\sigma_a) = (\sigma_f/\sigma_a)^2 \text{var}(\sigma_f) \quad (9)$$

and

$$\text{cov}(\sigma_f, \sigma_a) = (\sigma_f/\sigma_a) \text{var}(\sigma_f). \quad (10)$$

Introducing (9) and (10) into (8) reduces the latter relation to

$$\text{var}(c) \simeq \text{var}(\bar{\nu}) + (1 - \sigma_f/\sigma_a)^2 \text{var}(\sigma_f). \quad (11)$$

Relations (5), (6), and (11) illustrate the effect of adding information to the dependence of c on various parameters. Thus, relations (5) and (6) indicate that $\text{var}(c)$ increases when adding

increasingly more *independent* variates (on which c depends). On the other hand, relation (11) shows that when *correlated* (i.e., mutually dependent) variates are introduced, the total uncertainty, $\text{var}(c)$, could either increase or decrease, which underscores the fact that covariances play a significant role, and disregarding them can lead to erroneous results. As will be detailed in Sect. 2, most quantities of interest are not measured directly, but are inferred, in so-called *indirect measurements*, by means of mathematical relations involving quantities measured directly. In other words, the parameters of interest are certain combinations of the actually measured quantities. Therefore, when determining the uncertainties in the values of the parameters of interest, it is essential to take into account both the variances of the directly measured quantities, as well as the possible correlations between each pair of these directly measured quantities. Hence, caution must be exercised if results for indirectly measured quantities omit reporting correlations among the measured parameters, since if such correlations are disregarded, then even the reported resulting variances may be incorrect. The usefulness of such incomplete experimental data would be seriously limited for subsequent uses, since (for example) any computations using such incomplete data could not correctly determine the uncertainties in the respective computations.

The foregoing assessment of the relative uncertainties contributed by nuclear data indicates that these are of the order of $O(10^{-2})$. Comparing this order-of-magnitude with the uncertainties quoted in Table 1 for the experimentally measured multiplication factors, k_{eE} , which are of the order of $O(10^{-3})$, or with the uncertainties quoted for the “calculated multiplication factor,” $(k_{eff})_c$, which are of the order of $O(10^{-4})$, the following conclusions become apparent:

1. The quoted uncertainty of $O(10^{-4})$ for the “calculated multiplication factor,” $(k_{eff})_c$, must have originated solely from the convergence of the numerical Monte Carlo method;
2. The accuracy of the Monte Carlo numerical method is considerably higher than the accuracy of the corresponding measurements;
3. The uncertainties due to the nuclear data are a factor of 10 larger than the experimental uncertainties, and a factor of 10^2 larger than the convergence accuracy of the Monte Carlo method;
4. The uncertainties due to the nuclear data, which enter as parameters in the Monte Carlo computations, must have not been accounted for in the uncertainties quoted for the computational results in the above table;
5. The Monte Carlo method is sufficiently accurate for the purposes of these benchmark computations, so that the uncertainties due to the “numerical methods” can be neglected in subsequent discussion of these results;
6. The computations are not necessarily inconsistent with the corresponding measurements;
7. The nuclear data in the libraries could perhaps be improved by judiciously taking into account some, if not all, of experimentally measured results, since the experimental uncertainties are considerably smaller than the uncertainties to be expected when propagating the cross-section uncertainties through the neutronics computations.

In practice, the uncertainty arising in the computed effective multiplication factor $(k_{eff})_c$ due to uncertainties in the nuclear data is *not* determined in the simple-minded way used above for illustrating the role and order-of-magnitude played by cross section uncertainties. As indicated by (3), $(k_{eff})_c$ is numerically determined as the (largest) eigenvalue of the neutron transport equation. In mathematical terminology, $(k_{eff})_c$ is an implicit *functional* of the neutron flux which, in turn, depends on various partial cross sections of the isotopes contained in the

respective critical assembly. In turn, these cross sections are functions of the neutron energy. Formally, the functional dependence of $(k_{eff})_c$ can be written in the form $(k_{eff})_c = k_{eff}(\alpha)$, where the subscript c (denoting “computed”) has been dropped to simplify the notation, and where $\alpha = (\alpha_1, \dots, \alpha_N)$, denotes the N -component vector of *system parameters* (cross sections, number densities, etc.) that characterize the problem under consideration. Expanding $k_{eff}(p)$ in a Taylor series around the nominal parameter values (i.e., around the nominal values for the various cross sections) and retaining only the first-order terms yield the expression

$$\delta k_{eff} = \sum_{n=1}^N (\partial k_{eff} / \partial \alpha_n)^0 \delta \alpha_n, \quad \delta \alpha_n \equiv \alpha_n - \alpha_n^0. \quad (12)$$

The partial derivatives $s_n \equiv (\partial k_{eff} / \partial \alpha_n)^0$, where the superscript “zero” denotes that the respective quantity is evaluated at nominal parameter values, are called the *sensitivities* of $k_{eff}(\alpha)$ to (each of) the parameters α_n .

Denoting the covariance matrix of the parameters α by $C_\alpha \equiv \langle \delta \alpha \delta \alpha^T \rangle$, denoting by $S \equiv \{(\partial k_{eff} / \partial \alpha_1)^0, \dots, (\partial k_{eff} / \partial \alpha_N)^0\}$ the N -component vector of sensitivities, and integrating formally the square of (12) over the (unknown) joint probability distribution of all system parameters leads to the following expression for $\text{var}(k_{eff})$:

$$\text{var}(k_{eff}) = \langle (\delta k_{eff})^2 \rangle = S \langle \delta \alpha \delta \alpha^T \rangle S^T = S C_\alpha S^T. \quad (13)$$

The superscript “ T ” in (13) denotes “transposition,” a notation that will be used throughout this chapter. The relation (13) is colloquially known as the “*sandwich rule*” for propagating parameter uncertainties, and will also be derived in ► Sect. 2. The “sandwich rule” clearly highlights the fundamental role – as weighting functions – played by the sensitivities of the response of interest to the system’s parameters in determining the total uncertainty in the response (i.e., result) of interest. Hence, the accurate determination of these sensitivities is essential for computing the response uncertainties. In principle, the sensitivities could be estimated by recomputations using slightly perturbed parameter values in conjunction with the finite-difference approximation

$$s_n \equiv (\partial k_{eff} / \partial \alpha_n)^0 \simeq [k_{eff}(\alpha_1^0, \dots, \alpha_{n-1}^0, \alpha_n^0 + \delta \alpha_n, \alpha_{n+1}^0, \dots, \alpha_N^0) - k_{eff}(\alpha^0)] / \delta \alpha_n. \quad (14)$$

However, for large-scale problems involving many [$N \sim O(10^2)$ or more] parameters, the finite-difference approximation in (14) is neither practical (since it would require unrealistic computational resources) nor sufficiently accurate. There are, in principle, two classes of methods for computing sensitivities, namely *statistical methods*, which will be reviewed in ► Sect. 3, and *deterministic methods*, particularly the very efficient ASAP, which will be reviewed in ► Sect. 4. Notably, a global optimization and sensitivity analysis algorithm, which determines with probability one of the systems’ critical points (maxima, minima, or bifurcations) is presented in ► Sect. 4.5.

As can be surmised from the discussion thus far, the following types of information can be obtained in practice: (1) a mathematical simulation model for the physical problem at hand, relating the model parameters α , with nominal values (i.e., “means”) α^0 and covariances C_α ,

to the computed responses, $\mathbf{r}(\boldsymbol{\alpha})$; (2) relevant experiments for obtaining, in addition, “experimentally measured” responses, with mean values $\mathbf{r}_m$ and experimentally measured covariance matrices $\mathbf{C}_m$. In many cases, (some of) the measured responses may not be independent of, but could be correlated to (some of) the parameters; such correlations are generally characterized by symmetric response-parameter covariance matrices $\mathbf{C}_{r\alpha} = \mathbf{C}_{\alpha r}$. The goal is to use all of the available information, that is, the input parameters (occasionally called also the “differential” data), the measured responses (occasionally called the “integral” data), including their respective uncertainties (covariance matrices), and the computed responses and their sensitivities to parameters, to obtain “best-estimate” adjusted (calibrated) values $\boldsymbol{\alpha}^{be}$ for the parameters, and the corresponding “best-estimate” adjusted (calibrated) values $\mathbf{r}^{be}$ for the responses. The optimal combination of such information falls within the scope of *data assimilation and adjustment (calibration) procedures*, and the end products of these procedures are *best-estimate values for parameters and responses, as well as reduced uncertainties (i.e., “smaller” values for the variance-covariance matrices) for the best-estimate adjusted parameters and responses*.

Included within the scope of data assimilation and best-estimate adjustment procedures is also the important subject of *consistency* among experiments and computations. Thus, whenever experimental results are compared with corresponding computations or with independently measured similar results, the essential issue is to quantify the extent to which the respective sets of data agree with each other. Often, “reasonable agreement” is claimed on grounds of vague arguments and impressions, without substantial objective justifications. Consistency, however, must be indicated by a well-defined quantitative parameter which precisely determines the degree of agreement (or disagreement). Such a consistency indicator must reflect the underlying uncertainties and sensitivities, and also certain probability distributions. Unless all of the computations and experiments considered are reasonably consistent, the data assimilation and best-estimate adjustment (calibration) will yield questionable, if not altogether meaningless, end results.

As will be discussed in ► Sect. 5, the concept of prior probability distribution can be used to characterize the existing knowledge (or degree of belief) regarding each system parameter. The experiments and/or observations of the system responses provide additional knowledge about the system. The additional information introduced by drawing inferences from the observational data should improve the knowledge about the system. Combining *new information with prior knowledge* is customarily called “*data assimilation*.” Modern data assimilation is performed using *Bayesian inference* techniques. Furthermore, *the added knowledge, contained in the posterior probability density function, should lead to a reduction of uncertainties in both the responses and the system parameters, via the “best-estimate” adjustment procedure*.

The procedures for data assimilation and best-estimate adjustment of parameters are presented in ► Sect. 6. Under the assumptions discussed in ► Sect. 5, the Bayesian inference procedure leads to best-estimate adjusted (calibrated) parameter and responses, with reduced uncertainties, having the following expressions:

$$\boldsymbol{\alpha}^{be} = \boldsymbol{\alpha}^0 + (\mathbf{C}_{\alpha r} - \mathbf{C}_{\alpha} \mathbf{S}^T) \mathbf{C}_d^{-1} \mathbf{d}, \quad \mathbf{d} \equiv \mathbf{r}(\boldsymbol{\alpha}^0) - \mathbf{r}_m, \quad (15)$$

$$\mathbf{r}^{be} = \mathbf{r}_m + (\mathbf{C}_m - \mathbf{C}_{r\alpha} \mathbf{S}^T) \mathbf{C}_d^{-1} \mathbf{d}, \quad (16)$$

where $\mathbf{d} \equiv \mathbf{r}(\boldsymbol{\alpha}^0) - \mathbf{r}_m$ represents the vector of “deviations” between the computed and experimentally measured responses. Furthermore, the data assimilation and adjustment procedure

also yields best-estimate adjusted covariance matrices for the best-estimate adjusted parameter and responses, as follows:

$$\mathbf{C}_\alpha^{be} = \mathbf{C}_\alpha - \left(\mathbf{C}_{\alpha r} - \mathbf{C}_\alpha \mathbf{S}^T \right) \mathbf{C}_d^{-1} \left(\mathbf{C}_{r\alpha} - \mathbf{S} \mathbf{C}_\alpha \right), \quad (17)$$

$$\mathbf{C}_r^{be} = \mathbf{C}_m - \left(\mathbf{C}_m - \mathbf{C}_{r\alpha} \mathbf{S}^T \right) \mathbf{C}_d^{-1} \left(\mathbf{C}_m - \mathbf{S} \mathbf{C}_{\alpha r} \right), \quad (18)$$

$$\mathbf{C}_{\alpha r}^{be} = \mathbf{C}_{\alpha r} - \left(\mathbf{C}_{\alpha r} - \mathbf{C}_\alpha \mathbf{S}^T \right) \mathbf{C}_d^{-1} \left(\mathbf{C}_m - \mathbf{S} \mathbf{C}_{\alpha r} \right), \quad (19)$$

where

$$\mathbf{C}_d \equiv \left\langle \mathbf{d} \mathbf{d}^T \right\rangle = \mathbf{S} \mathbf{C}_\alpha \mathbf{S}^T - \mathbf{S} \mathbf{C}_{\alpha r} - \mathbf{C}_{r\alpha} \mathbf{S}^T + \mathbf{C}_m. \quad (20)$$

As indicated by the relations (17–19), the best estimate adjusted uncertainties are smaller than the original ones, since, in each case, one subtracts a positive definite matrix from the corresponding original covariance matrix. It will be shown in [Sect. 6](#) that the quantity $\chi^2 = \mathbf{d}^T \mathbf{C}_d^{-1} \mathbf{d}$ provides an overall *consistency indicator*. This quantity is actually the “chi-square” for the distribution of the M parameters (M may be equal to or less than the number of model parameters N) included in the adjustment. If $\chi^2/M \approx 1$, then the data sets in the adjustment are consistent; otherwise, particularly if $\chi^2/M \gg 1$, the respective data is inconsistent and must be rejected. Other useful “rejection gauges” are the individual “deviations” d_i , the “individual chi-square” indicator $\chi_{dia}^2 = d_i^2 (\mathbf{C}_{dii})^{-1}$, the “diagonal chi-square” indicator $\chi_{dia}^2 = d_i^2 (\mathbf{C}_d^{-1})_{ii}$, and various iterative schemes.

The implications of relations (17–19) can be readily examined for the simplest case, involving: (1) one parameter α , with nominally measured value α^0 and uncertainty $\mathbf{C}_\alpha = \sigma_\alpha^2$; and (2) one experimentally measured response r , with the nominally measured value r_m and uncertainty $\mathbf{C}_m = \sigma_m^2$, which is also correlated to α through the parameter-response correlation “matrix” $\mathbf{C}_{\alpha r} = \mathbf{C}_{r\alpha} = \rho \sigma_\alpha \sigma_m$, where $\rho \in [-1, 1]$ is the respective correlation factor. Consider that the nominal value of the computed result is r_c ; hence, the deviation between the computed and measured responses is simply $d \equiv (r_c - r_m)$. Note that the Greek letter σ is used in this example to denote “standard deviations” rather than “microscopic cross sections.”

For this simple case (i.e., one parameter and one measured response), the relation (20) reduces to

$$\mathbf{C}_d = S^2 \sigma_\alpha^2 - 2S \rho \sigma_\alpha \sigma_m + \sigma_m^2, \quad (21)$$

where S is the sensitivity of the computed response to the parameter α . In this simple case, the matrix-valued expressions in (15–19) are reduced, respectively, to the following algebraic expressions:

$$\alpha^{be} = \alpha^0 + (\rho \sigma_m - \sigma_\alpha S) \sigma_\alpha \mathbf{C}_d^{-1} d, \quad (22)$$

$$r^{be} = r_m + (\sigma_m - \rho \sigma_\alpha S) \sigma_m \mathbf{C}_d^{-1} d, \quad (23)$$

$$(\sigma_\alpha^{be})^2 = (1 - \rho^2) \sigma_\alpha^2 \sigma_m^2 \mathbf{C}_d^{-1}, \quad (24)$$

$$(\sigma_r^{be})^2 = S^2 (\sigma_\alpha^{be})^2 = S^2 (1 - \rho^2) \sigma_\alpha^2 \sigma_m^2 \mathbf{C}_d^{-1}, \quad (25)$$

$$\rho^{be} = 1. \quad (26)$$

If the response-parameter correlation were unknown, its effect on the adjusted (calibrated) best-estimate values can be quantified by considering ρ to vary within the interval $[-1, 1]$, and determining the value of ρ that is least favorable for the resulting best-estimate values. The worst-case value for ρ would maximize the value of the best-estimate calibrated uncertainty $(\sigma_r^{be})^2$. Such a worst-case adjustment would occur for that value of ρ which would cause the first-derivative of $(\sigma_r^{be})^2$, with respect to ρ , to vanish in the interval $[-1, 1]$. Taking the first derivative with respect to ρ in (25) and setting it to zero yields $\sigma_m - \rho \sigma_\alpha S = 0$; using this result in relations (22–25) leads to the following best-estimate calibrated values: $\alpha^{be} = \alpha^0 - (r_c - r_m)/S$, $(\sigma_\alpha^{be})^2 = \sigma_m^2/S^2$, $r^{be} = r_m$, and $(\sigma_r^{be})^2 = \sigma_m^2$.

Since the uncertainty in the experimentally measured response is usually less than the uncertainty in the computed response (i.e., $\sigma_m < S\sigma_\alpha$), it follows that $\sigma_\alpha^{be} < \sigma_\alpha$, which indicates that the best-estimate uncertainty for the best-estimate adjusted parameter is *reduced* (i.e., becomes smaller) even when the adjustment is made using a single consistently measured response. In addition, the best-estimate adjusted uncertainty for the best-estimate adjusted response, that is, σ_r^{be} is also reduced (in the worst-case, it is reduced to the value of σ_m). This simple example illustrates two of the most important points regarding data assimilation and best-estimate adjustment, in general: (1) the assimilation of consistent experimental data reduces uncertainties in the resulting best-estimate adjusted parameters and responses; and (2) even when the correlations between parameters and responses are neglected because they might be unknown, the assimilation and adjustment procedure is still worthwhile. Thus, consistent data assimilation and best-estimate adjustment is expected not only to improve agreement between calculation and measurement, but is also specifically expected to reduce uncertainties in calculated responses. To summarize: any additional consistent information reduces uncertainties. When relatively accurate experimental data is used, this reduction is very significant, indeed. In essence, all efforts should be aimed at using all available data to the fullest, ultimately generating the best possible “libraries,” comprising best-estimate parameter values for subsequent, predictive computations. Open issues and important avenues for further research aimed at alleviating the current shortcomings of data assimilation and best-estimate calibration procedures are presented in ► Sect. 7.

2 Measurement Uncertainties

2.1 Basic Concepts

The theory of measurement errors is a branch of metrology – the science of measurements. A *measurable quantity* is a property of phenomena, bodies, or substances that can be defined qualitatively and expressed quantitatively. Measurable quantities are also called *physical quantities*. A *measurement* is the process of finding the value of a physical quantity experimentally with the help of special devices called *measuring instruments*. The *result of a measurement* is a numerical value, together with a corresponding unit, for a physical quantity. Note that a measurement has three features:

1. The result of a measurement must always be a number expressed in sanctioned units of measurements. The purpose of a measurement is to represent a property of an object by a number;

2. A measurement is always performed with the help of some measuring instrument; measurement is impossible without measuring instruments;
3. A measurement is always an experimental procedure.

The *true value* of a measurable quantity is the value of the measured physical quantity, which, if it were known, would ideally reflect, both qualitatively and quantitatively, the corresponding property of the object. The theory of measurement relies on the following postulates:

1. The true value of the measurable quantity exists;
2. The true value of the measurable quantity is constant (relative to the conditions of the measurement); and
3. The true value cannot be found.

Since measuring instruments are imperfect, and since every measurement is an experimental procedure, the results of measurements cannot be absolutely accurate. This unavoidable imperfection of measurements is generally expressed as measurement inaccuracy, and is quantitatively characterized by measurement errors. Thus, the result of any measurement always contains an error, which is reflected by the deviation of the result of measurement from the true value of the measurable quantity. The measurement error can be expressed in absolute or relative form.

The *absolute measurement error*, δ , of an indication instrument is defined as the difference between the true value of the measured quantity, Q_t , and the measured value indicated by the instrument, Q_m , i.e., $\delta \equiv Q_t - Q_m$. The absolute error is a physical quantity that has the same units as the measurable quantity. Furthermore, the absolute error may be positive, negative, or be expressed as an interval that contains the measured value. The absolute error should not be confused with the absolute value of the (absolute) error; while the former may be positive or negative, the latter is always positive. Since absolute errors have units and depend, in general, on the value of the measured quantity, they are awkward to use as a quantitative characteristic of measurement accuracy. In practice, therefore, the error is usually expressed as a fraction (usually percent or per thousand) of the true value of the measurable quantity, by using the *relative measurement error*, ε , defined as $\varepsilon \equiv \delta/Q_t$.

Knowledge of measurement errors would allow statements about measurement accuracy, which is the most important quality of a measurement: the smaller the underlying measurement errors, the more accurate the respective measurement. The accuracy of a measurement can be characterized quantitatively by the inverse of the absolute value of relative error; for example, if the relative error of a measurement is $\pm 0.2\%$, then the accuracy of this measurement is 500. The accuracy of any particular measurement is determined not only by the accuracy of the measuring instruments employed, but also by the method of measurement employed and by the skill of the experimenter. However, since the true value of a measurable quantity is always unknown, the errors of measurements must be estimated theoretically, by computations, using a variety of methods, each with its own degree of accuracy.

Occasionally, measurement errors can be estimated before performing the actual measurement. Such measurements are called measurements with ante-measurement or *a priori estimation* of errors. On the other hand, measurements whose errors are estimated after the measurement are called measurements with post-measurement or *a posteriori estimation* of errors. When a physical quantity is measured repeatedly, the measuring instrument will not yield identical indications; rather, the indications will differ from one another, in a random manner. This random component of instrument error is referred to as the *repeatability* error

of a measuring instrument. For example, instruments with moving parts have repeatability errors caused by friction in support of the movable parts and by hysteresis phenomena. The length of the range of possible values of the random component of instrument error is called the *dead band*. In other words, the dead band is the maximum interval through which a stimulus may be changed in either direction without producing a change in the response of the measuring instrument. Since instruments are constructed in order to introduce regular relations and certainty into the phenomena under consideration, it is important to reduce the random errors of instruments to levels that are either negligibly small compared with other errors or are within prescribed limits of admissible errors for the respective type of measuring devices.

The properties of measuring instruments may change in time (e.g., because of component aging and environmental influences). Such time-dependent changes in any property of the measuring instrument are characterized by the instrument's instability and drift. Instrument instability can be standardized either by prescribing the value of the limits of permissible variations of the error over a definite period of time or by prescribing different error limits to different "lifetimes" of the instrument, after it is calibrated. On the other hand, the drift of an instrument is defined as the change (always in the same direction) that may occur in the output signal over a period of time that is significantly longer than the measurement time. The drift and instability of an instrument do not depend on the input signal but they can depend on external conditions. For this reason, the drift is usually determined in the absence of an input signal.

Measuring instruments are also characterized by their sensitivity, discrimination threshold, and resolution. Thus, the *sensitivity of an instrument* is defined as the ratio of the variation in the measured quantity at the output of the measuring instrument to variation of the input value of the quantity that causes the output value to change. The *discrimination threshold* is defined as the minimum variation in the input signal that causes an appreciable variation in the output signal. Finally, the *resolution of an instrument* is the smallest interval between two distinguishable neighboring discrete values of the output signal.

Measurements are customarily categorized as direct, indirect, and combined measurements. In *direct measurements*, the quantity to be measured interacts directly with the measuring instrument, and the value of the measured quantity is read from the instrument's indications. In *indirect measurements*, the value of the physical quantity is found by using a known dependence between the quantity and its basic properties which are themselves measured by means of direct, indirect, or combined measurements. For example, the density of a homogeneous solid body is inferred from an indirect measurement, which would consist of three steps: the first two steps would involve measuring directly the body's mass and volume, respectively, while the third step would involve taking the ratio of the measurements obtained in the first two steps.

Measurements performed with single observations are called *single measurements*, while measurements performed with repeated observations are called *multiple measurements*. Customarily, an indirect measurement is regarded as a single measurement if the value of each of the components of the indirectly measured quantity is found as a result of a single measurement. Thus, the indirect measurement of the density of a solid body (performed as mentioned in the previous example) would be considered a single measurement. Combined measurements can also be regarded as single measurements, if the number of measurements is equal to the number of unknowns, so that each unknown is determined uniquely from the system of equations obtained after performing the respective measurements.

2.2 Classification of Measurement Errors

As has been previously mentioned, the absolute measurement error $\delta \equiv Q_t - Q_m$ is defined as the difference between the true value, Q_t , of the quantity being measured and the measured value, Q_m , indicated by the instrument. This equation cannot be used directly to find the error of a measurement, however, since the true value of the measurable quantity is always unknown. (If the true value were known, then there would be no need for a measurement, of course.) Therefore, measurement errors must be estimated by using indirect data. For this purpose, measurement errors are traditionally classified according to their sources and their properties.

The basic sources of measurement errors are: errors arising from the method of measurement, errors due to the measuring instrument, and personal errors committed by the person performing the experiment. These errors are considered to be additive, so that the general form for the absolute measurement error δ is $\delta = \delta_m + \delta_i + \delta_p$, here δ_m , δ_i , and δ_p represent, respectively, the methodological error, the instrumental error, and the personal error. *Methodological errors* are caused by unavoidable discrepancies between the actual quantity to be measured and its model used in the measurement. Most commonly, such discrepancies arise from inadequate theoretical knowledge of the phenomena on which the measurement is based, and also from inaccurate and/or incomplete relations employed to find an estimate of the measurable quantity. *Instrumental measurement errors* are caused by imperfections of measuring instruments. The individual characteristics of the person performing the measurement may give rise to *personal errors*.

If the results of separate measurements of the same quantity differ from one another, and the respective differences cannot be predicted individually, then the error stemming from this scatter of the results is called *random error*. Random errors can be identified by repeatedly measuring the same quantity under the same conditions. On the other hand, a measurement error that remains constant or changes in a regular fashion when the measurements of that quantity are repeated is called a *systematic error*. Systematic errors can be discovered experimentally either by using a more accurate measuring instrument or by comparing a given result with a measurement of the same quantity, but performed by a different method. In addition, systematic errors are estimated by theoretical analysis of the measurement conditions, based on the known properties of the measuring instruments and the quantity being measured. Although the estimated systematic error can be reduced by introducing corrections, it is impossible to eliminate completely systematic errors from experiments. Ultimately, a residual error will always remain, and this residual error will then constitute the systematic component of the measurement error.

The quality of measurements that reflects the closeness of the results of measurements of the same quantity performed under the same conditions is called the *repeatability of measurements*. Good repeatability indicates that the random errors are small. On the other hand, the quality of measurements that reflects the closeness of the results of measurements of the same quantity performed under different conditions, that is, in different laboratories, at different locations, and/or using different equipment, is called the *reproducibility of measurements*. Good reproducibility indicates that both the random and systematic errors are small.

It is also customary to distinguish between gross or outlying errors and blunders. An error is *gross* or *outlying*, if it significantly exceeds the error justifiable by the conditions of the measurements, the properties of the measuring instrument employed, the method of measurement, and the qualification of the experimenter. For example, if the grid voltage affects the measurements

under consideration, then a sharp brief change in the grid voltage can produce an outlying error in a single experiment. Outlying errors in multiple measurements can be discovered by statistical methods and are usually eliminated from the final error analysis. On the other hand, *blunders* occur as a result of errors made by the experimenter. Examples of blunders are a slip of the pen when writing up the results of observations, an incorrect reading of the indications of an instrument, and so on. Blunders must be discovered by nonstatistical methods, and they must always be eliminated from the final results.

As has already been mentioned, a measurement error cannot be found directly by using its definition as an algorithm, since the true value of the measured quantity is unknown. The measurement error must be found by identifying its underlying sources and reasons, and by performing calculations based on the estimates of all components of the respective measurement inaccuracy. The smallest of the measurement errors are customarily referred to as *elementary errors* (of a measurement), and are defined as those components of the overall measurement error that are associated with a single source of inaccuracy for the respective measurement. The total measurement error is calculated, in turn, by using the estimates of the component elementary errors. Since a measurement error can only be calculated indirectly, based on models and experimental data, it is important to identify and classify the underlying elementary errors. This identification and classification is subsequently used to develop mathematical models for the respective elementary errors. Finally, the resulting (overall) measurement error is obtained by synthesizing the mathematical models of the underlying elementary errors. Even though it is sometimes possible to correct, partially, certain elementary errors (e.g., systematic ones), no amount or combination of corrections can produce an absolutely accurate measurement result; there always remains a residual error. In particular, the corrections themselves cannot be absolutely accurate, and, even after they are implemented, there remain residuals of the corresponding errors which cannot be eliminated and which later assume the role of elementary errors.

In the course of developing mathematical models for elementary errors, it has become customary to distinguish four types of elementary errors, namely, absolutely constant errors, conditionally constant errors, purely random errors, and quasi-random errors. Thus, *absolutely constant errors* are defined as elementary errors that remain the same (i.e., are constant) in repeated measurements performed under the same conditions, for all measuring instruments of the same type. For example, an absolutely constant error arises from inaccuracies in the formula used to determine the quantity being measured, once the limits of the respective inaccuracies have been established. Typical situations of this kind arise in indirect measurements of quantities determined by linearized or truncated simplifications of nonlinear formulas (e.g., analog/digital instruments where the effects of electro-motive forces are linearized). Based on their properties, *absolutely constant elementary errors are purely systematic errors*, since each such error has a constant value in every measurement, but this constant is nevertheless unknown. Only the limits of these errors are known. Therefore, *absolutely constant errors are modeled mathematically by a determinate (as opposed to random) quantity whose magnitude lies within an interval of known limits*.

Conditionally constant errors are, by definition, elementary errors that have definite limits (just like the absolutely constant errors) but (as opposed to the absolutely constant errors) such errors can vary within their limits due both to the nonrepeatability and the nonreproducibility of the results. A typical example of such an error is the measurement error due to the intrinsic error of the measuring instrument, which can vary randomly between fixed limits. Usually, *the conditionally constant error is mathematically modeled by a random quantity with a uniform*

probability distribution within prescribed limits. This mathematical model is chosen because the uniform distribution has the highest uncertainty (in the sense of information theory) among distributions with fixed limits. Note, in this regard, that the round-off error also has known limits, and this error has traditionally been regarded in mathematics as a random quantity with a uniform probability distribution.

Purely random errors appear in measurements due to noise or other random errors produced by the measuring device. The form of the distribution function for random errors can, in principle, be found using data from each multiple measurement. In practice, however, the number of measurements performed in each experiment is insufficient for determining the actual form of the distribution function. Therefore, *a purely random error is usually modeled mathematically by using a normal distribution characterized by a standard deviation that is computed from the experimental data.*

Quasi-random errors occur when measuring a quantity defined as the average of nonrandom quantities that differ from one another such that their aggregate behavior can be regarded as a collection of random quantities. In contrast to the case of purely random errors, though, the parameters of the probability distribution for quasi-random errors cannot be unequivocally determined from experimental data. Therefore, *a quasi-random error is modeled by a probability distribution with parameters (e.g., standard deviation) determined by expert opinion.*

Measurements must be reproducible; otherwise they lose their objective character and become useless. As has been discussed in the foregoing, the limits imposed by errors represent a measure of the irreproducibility of the respective measurement. It is therefore very important to strive to minimize measurement errors, which implies that they should be estimated as accurately as possible. The smaller the relative error, ε , of a given experiment, the more accurate (and, in this sense, the better) the measurement.

2.3 Probabilities and Relative Frequencies: Random and Systematic Errors

Although probabilities are not relative frequencies, the two concepts are certainly related. This relationship can be highlighted by considering n measurements of some quantity x , with discrete possible outcomes (such as faces of a die or channels of an analogue-to-digital converter). Thus, consider that the measurements (trials) are labeled $k = (1, 2, \dots, n)$, the observable outcomes x_v are labeled $\mu_l(R)$, ($l = 1, \dots, 4$), and the result of the k th trial is denoted by $R(\alpha_1, \dots, \alpha_k)$. Furthermore, the probabilities $\mu_k(\alpha_i)$, ($i = 1, \dots, k$; $k = 1, \dots, 4$) for all N^n possible outcomes of n trials are given and properly normalized such that $(\alpha_1, \dots, \alpha_k)$.

The relative frequency with which the result v occurs within the sequence $\{v_1, \dots, v_n\}$ can be written with the Kronecker δ symbol as $f_v = (1/n) \sum_{k=1}^n \delta_{vv_k}$.

Without any frequency data, inferences must be based on the given probabilities; consequently f_v can only be estimated from its expected value

$$\langle f_v \rangle = \frac{1}{n} \sum_{k=1}^n \left[\sum_{v_1} \cdots \sum_{v_n} P(v_1, \dots, v_n) \delta_{vv_k} \right] \equiv \frac{1}{n} \sum_{k=1}^n P(kv)$$

and its uncertainty (covariance matrix)

$$\langle f_\mu f_\nu \rangle = \frac{1}{n^2} \sum_{j=1}^n \sum_{k=1}^n \left[\sum_{v_1} \cdots \sum_{v_n} P(v_1, \dots, v_n) \delta_{\mu v_j} \delta_{\nu v_k} \right] \equiv \frac{1}{n^2} \sum_{j=1}^n \sum_{k=1}^n P(j\mu, k\nu),$$

where $P(k\nu)$ is the probability that the k th trial yields ν , and $P(j\mu, k\nu)$ is the joint probability that the j th trial yields μ and the k th trial yields ν . Thus, although relative frequencies are not probabilities, their expectation values can be calculated from probabilities as will be shown next. The special case $j = k$ describes one and the same measurement; hence, μ cannot differ from ν , implying that $P(k\mu, k\nu) = \delta_{\mu\nu} P(k\nu)$. The (co)variances of the estimated frequencies can therefore be written in the form

$$m \langle f_\mu f_\nu \rangle - \langle f_\mu \rangle \langle f_\nu \rangle = \frac{1}{n} (\delta_{\mu\nu} P_\nu - P_\mu P_\nu) + \left(1 - \frac{1}{n}\right) (P_{\mu\nu} - P_\mu P_\nu),$$

where $P_\nu \equiv (1/n) \sum_j P(j\nu)$ denotes the probability of observing the value x_ν in some unspecified single trial, and $P_{\mu\nu} \equiv (1/n(n-1)) \sum_j \sum_{k \neq j} P(j\mu, k\nu)$ denotes the probability of observing the values x_μ and x_ν in some unspecified pair of distinct trials, with $\sum_\nu P_\nu = 1$ and $\sum_{\mu, \nu} P_{\mu\nu} = 1$.

Note that the variances do not vanish in the limit of very many trials ("good statistics," $n \rightarrow \infty$) unless $P_{\nu\nu} = P_\nu^2$. The central limit theorem is valid only for completely independent, equivalent trials. For correlated trials, $P_{\mu\nu} \neq P_\mu P_\nu$, the variances cannot become smaller than $P_{\nu\nu} - P_\nu^2$ even for arbitrarily good statistics. This means that any correlation poses an irreducible limit on the accuracy with which frequencies can be predicted from probabilities. Note also that for uncorrelated measurements (i.e., when $P_{\mu\nu} = P_\mu P_\nu$), the relative frequencies are anticorrelated, since $\text{cov}(f_\mu, f_\nu) = -P_\mu P_\nu / n$ (unless $n \rightarrow \infty$). This is, of course, a consequence of the normalization condition: if one frequency varies in a certain sense, the others must be varied in the opposite sense in order to keep their normalized sum unaffected, $\sum_\nu f_\nu = 1$. The foregoing considerations underscore the fact that probabilities are not frequencies, but they enable us to predict frequencies and to assess the accuracy of the predictions.

To apply the relationship between frequencies and probabilities to a measured quantity x , consider that each measurement yields one of the N possible values x_ν (discretized by the electronics, for example, and differing from the true value because of errors). The sample mean $\bar{x} \equiv \sum_\nu f_\nu x_\nu$ is computed from observed frequencies f_ν for the values x_ν . Without additional observations, the expectation value of $\bar{x}$ and the corresponding uncertainty $\langle \bar{x}^2 \rangle$ are given by $\langle \bar{x} \rangle = \sum_\nu \langle f_\nu \rangle x_\nu$ and $\langle \bar{x}^2 \rangle = \sum_{\mu, \nu} \langle f_\mu f_\nu \rangle x_\mu x_\nu$, respectively. Using the previously obtained expressions for $\langle f_\nu \rangle$ and $\langle f_\mu f_\nu \rangle$ leads to the following expressions for the estimated mean $\langle \bar{x} \rangle$ and variance $\text{var}(\bar{x})$:

$$\langle \bar{x} \rangle = \langle x \rangle, \text{var}(\bar{x}) \equiv \langle \bar{x}^2 \rangle - \langle \bar{x} \rangle^2 = \frac{1}{n} (\langle x^2 \rangle - \langle x \rangle^2) + \left(1 - \frac{1}{n}\right) (\langle x, x \rangle - \langle x \rangle^2),$$

where $\langle x \rangle = \sum_\nu P_\nu x_\nu$ and $\langle x^2 \rangle = \sum_\nu P_\nu x_\nu^2$ are expectation values for a single unspecified measurement, whereas $\langle x, x \rangle = \sum_{\mu, \nu} P_{\mu\nu} x_\mu x_\nu$ arises from an unspecified pair of distinct, possibly correlated measurements. Thus, the variance of the sample average is the sum of two contributions, one from uncorrelated (statistical) errors of single measurements and the other one

from correlated (systematic) errors of pairs of measurements. Correlations are usually due to common errors such as errors in standards, detector calibration, electronic settings, and so forth. The foregoing derivation shows that the total error is obtained (correctly) by adding the statistical and the systematic (root-mean-square) errors (in quadrature).

In the special case when all n measurements are equivalent (“exchangeable measurements” in statistical jargon), the probabilities $P(k\nu)$, $P(j\mu, k\nu)$ must be the same for all trials and all pairs of trials: $P(k\nu) = P_\nu$, $P(j\mu, k\nu) = P_{\mu\nu}$ for $j \neq k$. When the various measurements are completely uncorrelated (which implies that all common and/or systematic errors are excluded), the relation $P_{\mu\nu} = P_\mu P_\nu$ holds, and therefore $\text{var } \bar{x} = (1/n) \text{var } x \rightarrow 0$, for $n \rightarrow \infty$. Thus, *for independent measurements, better statistics means more accuracy*.

On the other hand, if all measurements are fully correlated, all errors being common or systematic, the result x_ν of the first trial implies the same result for all following trials; this implies, in turn, that $P_{\mu\nu} = \delta_{\mu\nu} P_\nu$, leading to the result $\text{var } \bar{x} = \text{var } x$, for all n . In this case, *repetition of the measurement does not help at all. The uncertainty after any number of trials remains the same as it was after the first trial, because the unknown errors are always the same*.

In practice, both independent and correlated errors are usually present. The correlated errors constitute a “residual core” of uncertainty that remains undiminished no matter how often the measurement is repeated. The only way to reduce this residual error is to remeasure the quantity of interest by means of other techniques, with different instrumentation, geometry, perhaps even staff, in order to obtain systematic errors as different and as independent as possible from those of the other measurements. Eventually, the effect of several remeasurements with different techniques on the overall (systematic) uncertainty will be similar to the effect that a comparable number of repetitions with the same technique has on the uncorrelated (statistical) uncertainty.

2.4 Direct Measurements

When measuring a quantity *directly*, it is useful to distinguish between single and multiple measurements of the respective quantity. The *single direct measurement* is regarded as the basic form of measurement while *multiple direct measurements* can be regarded as being derived from single measurements. A priori, the error for a single measurement can be both systematic and random; however, after the measurement has been performed, the measurement error becomes a systematic error for that measurement. This is because the result of a measurement has a definite numerical value, and the difference between the measurement result and the true value of the measured quantity is a constant. Even if the entire error in a measurement were random, the error seemingly freezes after the measurement result is obtained; thus, the error loses its random character and becomes systematic. Each of the three components of the measurement, namely, the method of measurement, the measuring instrument, and the experimenter can be sources of systematic errors. Correspondingly, methodological, instrumental, and personal systematic errors are customarily distinguished from each other.

A systematic error that remains constant and is therefore repeated in each observation or measurement is called a *constant systematic error*; for example, such an error will be present in measurements performed using balances, resistors, or similar instruments. The personal errors made by experienced experimenters can also be classified as constant (personal errors made by inexperienced experimenters, however, are considered random). Errors which increase (or

decrease) throughout the measurement time are called *progressing errors*. Errors that vary with a definite period are called *periodic errors*.

It is very difficult to identify systematic errors; for example, variable systematic errors can be identified by using statistical methods, correlation, and regression analysis. Systematic errors can also be identified by measuring the same quantity using two different instruments (methods) or by measuring periodically a known (instead of an unknown) quantity. If a systematic error has been identified, then it can usually be estimated and eliminated. However, making rational estimates of the magnitude of the residual systematic errors and, in particular, assigning consistent levels of confidence to these residual errors is an extremely difficult task. In practice, therefore, *residual systematic errors are assumed to follow a continuous uniform distribution, within ranges that are conservatively estimated based on experience and expert judgment*.

Multiple direct measurements are usually needed for measuring the average value of some parameter; for reducing the effects of random errors associated with the measuring instruments; for investigating a new phenomenon (to determine relationships between the quantities characterizing the respective phenomenon and connections to other physical quantities); and for developing new measuring instruments. Under certain restrictions on the measurement data, the methods of mathematical statistics provide means for analyzing observations and estimating measurement errors from multiple measurements. Thus, direct multiple measurements that are free of systematic errors (i.e., in which only random errors occur) can be analyzed by statistical methods directly, without additional considerations. In many practical situations, though, the mathematical restrictions required by mathematical statistics are not entirely fulfilled; hence, it is often necessary to develop practical methods for analyzing such situations individually, case by case.

When the *random character of the observational results is caused by measurement errors, the respective observations are assumed to have a normal distribution*. This assumption rests on two premises, namely: (1) since measurement errors consist of many components, the central limit theorem implies a normal distribution for such errors; and (2) measurements are performed under controlled conditions, so that the distribution function of their error is actually bounded. Hence, approximating a bounded distribution by a normal distribution (for which the random quantity can take any real value) is a conservative procedure since such an approximation leads to larger confidence intervals than would be obtained if the true bounded distribution were known. Nevertheless, the hypothesis that the distribution of the observations is normal must be verified, since the measured results do not always correspond to a normal distribution. For example, *when the measured quantity is an average value, the distribution of the observations can have any form*.

In general, both the systematic and random components of the error must be estimated. Although repeating the measurements yields information about the random components of the error, information about the systematic component cannot be extracted from the measurements themselves. Hence, the systematic errors are estimated from information about the properties of the measuring instruments employed, the method of measurement, and the conditions under which the measurements are performed. Although the random error can only be estimated *a posteriori*, the systematic error can also be estimated *a priori*. Note that the random components of all conditionally constant errors become *a posteriori* part of the random error of the respective measurement. Thus, the remaining parts of conditionally constant errors in multiple measurements become purely systematic errors. However, the values of these errors can vary in repeated measurements of the same quantity, even if the measurements are performed by the same method.

2.5 Indirect Measurements: Propagation of Errors

An *indirect measurement* is a measurement in which the value of the unknown quantity is calculated by using matched measurements of other quantities, called measured arguments or (briefly) *arguments*, which are related through a known relation to the measured quantity. From the perspective of conducting a measurement, the indirect measurements can also be divided into two classes, namely, *single indirect measurements* (in which all arguments are measured once only) and *multiple indirect measurements* (in which all arguments are measured several times).

In an indirect measurement, the *true but unknown value of the measured quantity or response*, denoted by R , is related to the *true but unknown values of arguments*, denoted as $(\alpha_1, \dots, \alpha_k)$, by a *known relationship (i.e., function) f* . This relationship is called the *measurement equation*, and can be generally represented in the form

$$R = f(\alpha_1, \dots, \alpha_k). \quad (27)$$

The specific forms of measurement equations can be considered as mathematical models of specific indirect measurements. It is very important to note here that the measurement equation can be interpreted to represent not only results of indirect measurements but also *results of computations*. In this interpretation, $(\alpha_1, \dots, \alpha_k)$ are considered to be the parameters underlying the respective computation, R is considered to represent the result or response of the computation, while f represents not only the explicit relationships between parameters and response but also represents implicitly the relationships among the parameters and the independent and dependent variables comprising the respective mathematical model.

In practice, the *nominal parameter values*, $(\alpha_1^0, \dots, \alpha_k^0)$, are known together with their *uncertainties or errors*, $(\delta\alpha_1, \dots, \delta\alpha_k)$. The nominal parameter values are given by their respective *expectations*, while the associated errors and/or uncertainties are given by their respective *standard deviations*. Processing the experimental data obtained in an indirect measurement is performed with the same objectives as for direct measurements, namely, to calculate the expected value, $E(R)$, of the measured response R , and to calculate the error and/or uncertainty, including confidence intervals, associated with $E(R)$. Calculating the expected value, $E(R)$, of the measured and/or calculated response R , and calculating the various higher-order moments of the distribution of R (variances and covariances, skewness, kurtosis), together with confidence intervals associated with $E(R)$, are the objectives of a procedure called the method of *propagation of moments* or *propagation of errors*, which will be presented in the sequel.

As indicated by the measurement equation, the measured (or calculated) system response R (i.e., the result of an indirect measurement or the result of a calculation) is considered to be a real-valued function of k system parameters, denoted as $(\alpha_1, \dots, \alpha_k)$; without loss of generality, these parameters can be considered to be real scalars. As discussed in the previous section, the *true values* of the parameters $(\alpha_1, \dots, \alpha_k)$ are *not* known; only their *nominal values*, $(\alpha_1^0, \dots, \alpha_k^0)$, and corresponding *uncertainties or errors*, $(\delta\alpha_1, \dots, \delta\alpha_k)$, are known. Usually, the nominal parameter values are taken to be the expected parameter values, while the associated errors and/or uncertainties are given by their respective standard deviations. The relative uncertainties $\delta\alpha_i/\alpha_i^0$ are usually symmetrical around α_i^0 , and smaller than unity. Therefore, the measurement equation (or computational model) can be written in the form

$$R = R(\alpha_1, \dots, \alpha_k) = R(\alpha_1^0 + \delta\alpha_1, \dots, \alpha_k^0 + \delta\alpha_k). \quad (28)$$

In the functional relation above, R is used in the dual role of both a (random) function and the numerical realization of this function. Expanding $R(\alpha_1^0 + \delta\alpha_1, \dots, \alpha_k^0 + \delta\alpha_k)$ in a Taylor series around the nominal values $\alpha^0 = (\alpha_1^0, \dots, \alpha_k^0)$ and retaining the terms up to the n th order in the variations $\delta\alpha_i \equiv (\alpha_i - \alpha_i^0)$ around α_i^0 gives:

$$\begin{aligned} R(\alpha_1, \dots, \alpha_k) &\equiv R(\alpha_1^0 + \delta\alpha_1, \dots, \alpha_k^0 + \delta\alpha_k) \\ &= R(\alpha^0) + \sum_{i_1=1}^k \left(\frac{\partial R}{\partial \alpha_{i_1}} \right)_{\alpha^0} \delta\alpha_{i_1} + \frac{1}{2} \sum_{i_1, i_2=1}^k \left(\frac{\partial^2 R}{\partial \alpha_{i_1} \partial \alpha_{i_2}} \right)_{\alpha^0} \delta\alpha_{i_1} \delta\alpha_{i_2} \\ &\quad + \frac{1}{3!} \sum_{i_1, i_2, i_3=1}^k \left(\frac{\partial^3 R}{\partial \alpha_{i_1} \partial \alpha_{i_2} \partial \alpha_{i_3}} \right)_{\alpha^0} \delta\alpha_{i_1} \delta\alpha_{i_2} \delta\alpha_{i_3} + \dots \\ &\quad + \frac{1}{n!} \sum_{i_1, i_2, \dots, i_n=1}^k \left(\frac{\partial^n R}{\partial \alpha_{i_1} \partial \alpha_{i_2} \dots \partial \alpha_{i_n}} \right)_{\alpha^0} \delta\alpha_{i_1} \dots \delta\alpha_{i_n} + \dots \end{aligned} \quad (29)$$

Using the above Taylor-series expansion, the various moments of the random variable $R(\alpha_1, \dots, \alpha_k)$, namely, its mean, variance, skewness, and kurtosis, are calculated by considering that the system parameters $(\alpha_1, \dots, \alpha_k)$ are random variables distributed according to a joint (albeit unknown) probability density function $p(\alpha_1, \dots, \alpha_k)$. The parameters' means (expectation values), variances, and covariances are as follows:

$$E(\alpha_i) = \alpha_i^0, \quad (30)$$

$$\text{var}(\alpha_i, \alpha_i) \equiv \sigma_i^2 \equiv \int_{S_\alpha} (\alpha_i - \alpha_i^0)^2 p(\alpha_1, \dots, \alpha_k) d\alpha_1 d\alpha_2 \dots d\alpha_k, \quad (31)$$

$$\text{cov}(\alpha_i, \alpha_j) \equiv \int_{S_\alpha} (\alpha_i - \alpha_i^0)(\alpha_j - \alpha_j^0) p(\alpha_1, \dots, \alpha_k) d\alpha_1 d\alpha_2 \dots d\alpha_k. \quad (32)$$

The procedure outlined above is called the *method of propagation of errors* or *propagation of moments*, and the resulting equations for the various moments of $R(\alpha_1, \dots, \alpha_k)$ are called the *moment propagation equations*.

For large complex systems, with many parameters, it is often impractical to consider the nonlinear terms in the Taylor expansion of the response. In such cases, response $R(\alpha_1, \dots, \alpha_k)$ is taken to be a *linear function of the parameters* $(\alpha_1, \dots, \alpha_k)$, that is,

$$R(\alpha_1, \dots, \alpha_k) = R(\alpha^0) + \sum_{i=1}^k \left(\frac{\partial R}{\partial \alpha_i} \right)_{\alpha^0} \delta\alpha_i = R^0 + \sum_{i=1}^k S_i \delta\alpha_i, \quad (33)$$

where $R^0 \equiv R(\alpha^0)$, while $S_i \equiv (\partial R / \partial \alpha_i)_{\alpha^0}$ denotes the *sensitivity of the response* $R(\alpha_1, \dots, \alpha_k)$ to the parameter α_i . The *mean value* of $R(\alpha_1, \dots, \alpha_k)$ is obtained from (33) as

$$\begin{aligned} E(R) &\equiv \int_{S_\alpha} \left(\sum_{i=1}^k S_i \delta\alpha_i \right) p(\alpha_1, \dots, \alpha_k) d\alpha_1 d\alpha_2 \dots d\alpha_k + R^0 \\ &= \sum_{i=1}^k S_i \int_{S_\alpha} (\alpha_i - \alpha_i^0) p(\alpha_1, \dots, \alpha_k) d\alpha_1 d\alpha_2 \dots d\alpha_k + R^0 \\ &= R^0. \end{aligned} \quad (34)$$

The various moments of $R(\alpha_1, \dots, \alpha_k)$ can be calculated by using (33) and (34); thus, the l th central moment $\mu_l(R)$ of $R(\alpha_1, \dots, \alpha_k)$ is obtained as the following k -fold integral over the domain S_α of the parameters α :

$$\mu_l(R) \equiv E\left((R - E(R))^l\right) = \int_{S_\alpha} \left(\sum_{i=1}^k S_i \delta \alpha_i\right)^l p(\alpha_1, \dots, \alpha_k) d\alpha_1 d\alpha_2 \dots d\alpha_k. \quad (35)$$

The variance of $R(\alpha_1, \dots, \alpha_k)$ is calculated by setting $l = 2$ in (35) and by using the result obtained (34), as follows:

$$\begin{aligned} \mu_2(R) \equiv \text{var}(R) &\equiv E\left((R - R^0)^2\right) \\ &= \sum_{i=1}^k S_i^2 \text{var}(\alpha_i) + 2 \sum_{i \neq j=1}^k S_i S_j \text{cov}(\alpha_i, \alpha_j) \\ &= S V_\alpha S^T, \end{aligned} \quad (36)$$

where the superscript “ T ” denotes transposition, the column vector $S = (S_1, \dots, S_k)$, with components $S_i = (\partial R / \partial \alpha_i)_{\alpha^0}$, denotes the *sensitivity vector*, and V_α denotes the *covariance matrix* for the parameters $(\alpha_1, \dots, \alpha_k)$, with elements defined as

$$(V_\alpha)_{ij} = \begin{cases} \text{cov}(\alpha_i, \alpha_j) = \rho_{ij} \sigma_i \sigma_j, & i \neq j, \\ \text{var}(\alpha_i) = \sigma_i^2, & i = j. \end{cases} \quad \rho_{ij} \equiv \text{correlation coefficient}$$

The last line in the relation (36) is colloquially known as the *sandwich rule*. If the system parameters are uncorrelated, the relation (27) takes on the simpler form

$$\text{var}(R) = \sum_{i=1}^k S_i^2 \text{var}(\alpha_i) = \sum_{i=1}^k S_i^2 \sigma_i^2. \quad (37)$$

The above concepts can be readily extended from a single response to n responses that are functions of the parameters $(\alpha_1, \dots, \alpha_k)$. In vector notation, the n responses are represented as the column vector $R = (R_1, \dots, R_n)$. In this case, the vector-form equivalent of relation (33) is the following linear, first-order Taylor expansion of $R(\alpha)$:

$$R(\alpha^0 + \delta \alpha) = R(\alpha^0) + \delta R \cong R(\alpha^0) + S \delta \alpha, \quad (38)$$

where S is a rectangular matrix of order $n \times k$ with elements $(S)_{ji} = \partial R_j / \partial \alpha_i$ representing the sensitivity of the j th response to the i th system parameter.

The expectation $E(R)$ of R is obtained by following the same procedure as that leading to (34), to obtain

$$E(R) = R^0. \quad (39)$$

The covariance matrix V_R for R is obtained by following the same procedure as that leading to (36), to obtain

$$V_R = E(S \delta \alpha (S \delta \alpha)^T) = S E(\delta \alpha \delta \alpha^T) S^T = S V_\alpha S^T. \quad (40)$$

Note that the relation (40) has the same “sandwich” form as (36) for a single response.

The equations for the propagation of higher-order moments become increasingly complex and are seldom used in practice. For example, for a single response $R(\alpha_1, \dots, \alpha_k)$ and *uncorrelated parameters* $(\alpha_1, \dots, \alpha_k)$, the respective propagation of moments equations can be obtained from (29), after a considerable amount of algebra, as follows:

$$E(R) = R(\alpha_1^0, \dots, \alpha_k^0) + \frac{1}{2} \sum_{i=1}^k \left\{ \frac{\partial^2 R}{\partial \alpha_i^2} \right\}_{\alpha^0} \mu_2(\alpha_i) + \frac{1}{6} \sum_{i=1}^k \left\{ \frac{\partial^3 R}{\partial \alpha_i^3} \right\}_{\alpha^0} \mu_3(\alpha_i) \\ + \frac{1}{24} \sum_{i=1}^k \left\{ \frac{\partial^4 R}{\partial \alpha_i^4} \right\}_{\alpha^0} \mu_4(\alpha_i) + \frac{1}{24} \sum_{i=1}^{k-1} \sum_{j=i+1}^k \left\{ \frac{\partial^4 R}{\partial \alpha_i^2 \partial \alpha_j^2} \right\}_{\alpha^0} \mu_2(\alpha_i) \mu_2(\alpha_j); \quad (41)$$

$$\mu_2(R) = \sum_{i=1}^k \left\{ \left(\frac{\partial R}{\partial \alpha_i} \right)^2 \right\}_{\alpha^0} \mu_2(\alpha_i) + \sum_{i=1}^k \left\{ \frac{\partial R}{\partial \alpha_i} \frac{\partial^2 R}{\partial \alpha_i^2} \right\}_{\alpha^0} \mu_3(\alpha_i) + \frac{1}{3} \sum_{i=1}^k \left\{ \frac{\partial R}{\partial \alpha_i} \frac{\partial^3 R}{\partial \alpha_i^3} \right\}_{\alpha^0} \mu_4(\alpha_i) \\ + \frac{1}{4} \sum_{i=1}^k \left\{ \left(\frac{\partial^2 R}{\partial \alpha_i^2} \right)^2 \right\}_{\alpha^0} [\mu_4(\alpha_i) - (\mu_2(\alpha_i))^2]; \quad (42)$$

$$\mu_3(R) = \sum_{i=1}^k \left\{ \left(\frac{\partial R}{\partial \alpha_i} \right)^3 \right\}_{\alpha^0} \mu_3(\alpha_i) + \frac{3}{2} \sum_{i=1}^k \left\{ \left(\frac{\partial R}{\partial \alpha_i} \right)^2 \frac{\partial^2 R}{\partial \alpha_i^2} \right\}_{\alpha^0} [\mu_4(\alpha_i) - (\mu_2(\alpha_i))^2]; \quad (43)$$

$$\mu_4(R) = \sum_{i=1}^k \left\{ \left(\frac{\partial R}{\partial \alpha_i} \right)^4 \right\}_{\alpha^0} [\mu_4(\alpha_i) - 3(\mu_2(\alpha_i))^2] + 3[\mu_2(R)]^2. \quad (44)$$

In the relations (41–44), the quantities $\mu_l(R)$, $(l = 1, \dots, 4)$, denote the respective *central moments* of the response $R(\alpha_1, \dots, \alpha_k)$, while the quantities $\mu_k(\alpha_i)$, $(i = 1, \dots, k; k = 1, \dots, 4)$ denote the respective central moments of the parameters $(\alpha_1, \dots, \alpha_k)$. Note that $E(R) \neq R^0$ when the response $R(\alpha_1, \dots, \alpha_k)$ is a nonlinear function of the parameters $(\alpha_1, \dots, \alpha_k)$. As has been already emphasized, the relations (41–44) are valid only for uncorrelated parameters.

It is important to emphasize that the “propagation of moments” equations are used not only for processing experimental data obtained from indirect measurements, but are also used for performing statistical analysis of computational models. In the latter case, the “propagation of errors” equations provide a systematic way of obtaining the uncertainties in computed results, arising not only from uncertainties in the parameters that enter the respective computational model but also from the numerical approximations themselves. The computation of sensitivities and, subsequently, uncertainties in results produced by various models (algebraic, differential, integrals, etc.) are the objectives of 🔍 Sects. 3 and 🔍 4.

2.6 Glossary

Absolute error (of a measuring instrument): The difference between the value of the measured quantity obtained by using a measuring instrument and the true (but unknown) value of the measured quantity.

Absolutely constant elementary error: An elementary error that retains the same value in repeated measurements performed under the same conditions. The value of an absolutely constant error is unknown but its limits can be estimated.

Accuracy of measurement: A qualitative expression of the closeness of the result of a measurement to the true value of the measured quantity.

Accuracy of a measuring instrument: The ability of a measuring instrument to produce measurements whose results are close to the true value of the measured quantity.

Combined measurement: Measurement of several quantities of the same kind, using results from (and/or combinations of) direct measurements.

Conditionally constant elementary error (of a measurement): An elementary error, having definite limits, which varies in repeated measurements performed under the same conditions or with different measuring instruments of the same type. These limits can be calculated or estimated.

Dead band: Maximum interval through which a stimulus may be changed in either direction without producing a change in the response of a measuring instrument.

Drift: A slow variation in time of the output of a measuring instrument, independently of the respective stimulus.

Elementary error (of a measurement): A component of error or uncertainty of a measurement associated with a single source of inaccuracy of the measurement.

Error (of a measurement): The deviation of the result of a measurement from the true value of the measured quantity; the error is expressed in absolute or relative form.

Inaccuracy (of a measurement): A qualitative characteristic of the deviation of a measurement result from the true value of the measured quantity. Quantitatively, inaccuracy can be characterized either as a measurement error or as a measurement uncertainty.

Indirect measurement: A measurement in which the value of the measured quantity is calculated by using measurements of other quantities that are connected to the measured quantity by a known relation.

Intrinsic error: The error of a measuring instrument, determined under reference conditions.

Measurement: The set of experimental operations that are performed using technical products (measuring instruments) for the purpose of finding the value of a physical quantity.

Measuring instrument: A technical product with standardized metrological characteristics.

Measuring standard: A measuring instrument intended to materialize and/or conserve a unit of a physical quantity in order to transmit its value to other measuring instruments.

Metrology: Science of measurement: an applied science that includes knowledge of measurements of physical quantities.

Normal operating conditions: Conditions within which a measuring instrument is designed to operate so that its metrological characteristics lie within specified limits.

Primary standard: A measuring standard that has the highest accuracy (in a country).

Random error (of a measurement): A component of the inaccuracy of a measurement that varies in an unpredictable way in the course of repeated measurements of the same measured quantity under the same conditions.

Relative error: Absolute error divided by the true value of the measured quantity. In practice, the true (but unknown) value is replaced by the measurement result.

Repeatability of a measurement: The closeness of agreement among several consecutive measurements of the same quantity, performed under the same operating conditions with the same measuring instruments, over a short period of time.

Reproducibility of a measurement: The closeness of agreement among repeated measurements for the same measured quantities performed in different locations, under different operating conditions, or over a long period of time.

Resolution: The smallest, still distinguishable interval between two adjacent values of the output signal of a measuring instrument.

Result of measurement: The value obtained by measurement of a quantity. The measurement result is expressed as a product of a numerical value and a proper unit.

Sensitivity of a measuring instrument: The change in the response of a measuring instrument divided by the corresponding change in the stimulus.

Systematic error (of measurement): A component of the inaccuracy of measurement that remains constant or varies in a predictable way in the course of repeated measurements of the same measured quantity.

True value: The value of a measured quantity that (if it were known) would ideally reflect, qualitatively and quantitatively, the respective property of the quantity of interest.

Uncertainty of measurement: An interval within which the true value of a measured quantity would lie with a given probability. Uncertainty is defined with its limits and corresponding confidence probability, and can be expressed in absolute or relative form.

3 Statistical Methods for Sensitivity and Uncertainty Analysis

The purpose of this section is to review the salient features, highlighting relative strengths and weaknesses, of the most popular screening and statistical methods for sensitivity and uncertainty analysis. These statistical procedures can be classified as follows: first- and second-order reliability algorithms (*FORM* and *SORM*, respectively); screening design methods (classical one-at-a-time experiments, global one-at-a-time design methods, systematic fractional replicate designs, and sequential bifurcation designs); sampling-based methods (random sampling, stratified importance sampling, and Latin Hypercube sampling); and variance-based methods (correlation ratio-based methods, the Fourier amplitude sensitivity test, and Sobol's method).

The salient features of the first- and second-order *reliability algorithms* (*FORM* and *SORM*, respectively) are briefly reviewed in [Sect. 3.1](#). [Section 3.2](#) reviews representative *screening design methods*; these methods refer to preliminary numerical experiments designed to identify the parameters that have the largest influence on a particular model response. The objective of screening is to arrive at a *short list* of important factors, based on the assumption that the number of parameters that are truly important to the model response is small by comparison to the total number of parameters underlying the model. Falling within the simplest class of screening designs are the so-called *one-at-a-time* (*OAT*) experiments, in which the impact of changing the values of each parameter is evaluated in turn. However, the results of a classical *OAT* experiment are meaningful only if the model's input-output relation can be adequately represented by a first-order polynomial in the model's parameters. If the model is affected by nonlinearities, as is often the case in practice, then parameter changes around the "control" scenario could provide drastically different "sensitivities," depending on the chosen "control" scenario. Several alternative designs have been proposed to alleviate this severe limitation of classical *OAT* designs; among the most popular alternatives are the *systematic fractional replicate design* (*SFRD*), the *global OAT* design methods, and the *sequential bifurcation* (*SB*) design. All of these methods are computationally very intensive, which severely limits the amount of reliable information that can be extracted from a screening design. Most importantly, since the importance of parameters is not obvious a priori (and may often be counterintuitive) in

large-scale, complex models, screening design methods may be a priori inadequate to identify correctly the truly important parameters.

The salient features of the most popular *sampling-based methods*, namely *random sampling*, *stratified importance sampling*, and *Latin Hypercube sampling*, are reviewed in ► Sect. 3.3. In particular, Latin Hypercube sampling provides a compromise importance sampling when a priori knowledge of the relationships between the sampled parameters and predicted responses is not available. The very first step in all sampling-based uncertainty and sensitivity analysis methods is crucial to the final results produced by these methods, since this initial step defines, via “expert opinions,” the distributions used to characterize the subjective uncertainty. Hence, the proper assignment of these distributions is essential for avoiding spurious results.

Finally, three of the most popular *variance-based methods* for statistical uncertainty and sensitivity analysis, namely *the correlation ratio-based methods*, the *Fourier Amplitude Sensitivity Test (FAST)*, and *Sobol’s method*, are discussed in ► Sect. 3.4. In particular, it is noted that the correlation ratio, the FAST, and Sobol’s methods do *not* make the *a priori* assumption that the input model parameters are linearly related to the model’s response; this is in contradistinction to the sampling-based methods reviewed in ► Sect. 3.3.

It is important to note that all statistical uncertainty and sensitivity analysis methods first commence with the “uncertainty analysis” stage, and only subsequently proceed to the “sensitivity analysis” stage; this procedural path is the reverse of the procedural (and conceptual) path underlying the deterministic methods of sensitivity and uncertainty analysis, where the sensitivities are determined prior to using them for uncertainty analysis. Furthermore, the actual response sensitivities to parameters cannot be computed exactly by using statistical methods; this can be done only by using *deterministic methods*, which will be reviewed in ► Sect. 4.

3.1 Reliability Algorithms: FORM and SORM

In many practical problems, the primary interest of the analyst may be focused on a particular mode of failure of the system under consideration, while the detailed spectrum of probabilistic outcomes may be of secondary concern. For such problems, the so-called reliability algorithms provide relatively fast and economical answers regarding the particular mode of failure of the system under consideration. The typical problems that can be analyzed by using reliability algorithms must be characterized by a mathematical model (whose solution can be obtained analytically or numerically), by input parameters that can be treated as being affected by subjective (epistemic) uncertainties, and by a threshold level that specifies mathematically the concept of “failure.” The reliability algorithms most often used are known as the first-order reliability methods (*FORM*) and second-order reliability methods (*SORM*), respectively. Both of these methods use optimization algorithms based on the mathematical model and the response functional that defines failure to seek “the most likely failure point” in the space of uncertain parameters. Once this most likely failure point, referred to as the “design point,” has been determined, the probability of failure is approximately evaluated by fitting a first- (or second-) order surface at that point. As with many optimization algorithms, the *FORM* and *SORM* algorithms are susceptible to non-convergence or to convergence to an erroneous design point, particularly when the failure probability approaches the extreme values of 0.0 or 1.0. Therefore, the numerical optimization algorithm and convergence tolerances should be tailored, whenever possible, to the specific problem under investigation.

3.2 Design of Experiments and Screening Design Methods

Design of Experiments was introduced by Fischer (1935), and calls for selecting those combinations of parameter values, called *design points*, which will provide the most information on the input–output relationship embodied by a model in the presence of parameter variations. However, the basic question underlying this selection is often a circular one: if the response function were known, then it would be easy to select the optimal design points, but the response is actually the object of the investigation, to begin with. Often used in practice is the so-called *Factorial Design (FD)*, which aims at measuring the additive and interactive effects of input parameters on the response. A *FD* simulates all possible combinations of assigned values, l_i , called *levels*, to each (uncertain) system parameter α_i . Thus, even though a *FD* can account for interactions among parameters, the computational cost required by a *FD* is $l_1 l_2 \dots l_I$, where I denotes the total number of parameters in the model; such a computational effort is prohibitively high for large-scale systems. A useful alternative is the *Fractional Factorial Design (FFD)* introduced by Box and Draper (1987), which assumes a priori that higher-order interactions between parameters are unimportant.

Screening design methods refer to preliminary numerical experiments designed to identify the parameters that have the largest influence on a particular model response. The objective of screening is to arrive at a *short list* of important factors. In turn, this objective can only be achieved if the underlying numerical experiments are judiciously designed. An assumption often used as a working hypothesis in screening design is the assumption that the number of parameters that are truly important to the model response is small by comparison to the total number of parameters underlying the model. This assumption is based on the idea that the influence of parameters in models follows Pareto's law of income distribution within nations, characterized by a few, very important parameters and a majority on noninfluential ones. Since screening designs are organized to deal with models containing very many parameters, they should be computationally economical. There is an inevitable tradeoff, however, between computational costs and information extracted from a screening design. Thus, computationally economical methods often provide only qualitative, rather than quantitative information, in that they provide a parameter importance ranking rather than a quantification of how much a given parameter is more important than another.

Falling within the simplest class of screening designs are the so-called *one-at-a-time (OAT)* experiments (Daniel 1973), in which the impact of changing the values of each parameter is evaluated in turn. The *standard OAT* experiment is defined as the experiment that uses standard or nominal values for each of the I parameters underlying the model. The combination of nominal values for the I parameters is called the *control experiment* (or *scenario*). Two extreme values are then selected to represent the range of each of the I parameters. The nominal values are customarily selected at the midway between the two extremes. The magnitudes of the *residuals*, defined as the difference between the perturbed and nominal response (output) values, are then compared to assess which factors are most significant in affecting the response.

Although the strategy described above is often used in practice, it is not the only one; *OAT* designs can be classified (Daniel 1973) into five categories, as follows: (1) *standard OAT* designs, which vary one factor from a standard condition; (2) *strict OAT* designs, which vary one factor from the condition of the last preceding experimental run; (3) *paired OAT* designs, which produce two observations and, therefore, one simple comparison at a time; (4) *free OAT* designs, which make each new computation under new conditions; and (5) *curved OAT* designs, which

produce a subset of results by varying only one parameter that is easy to vary. In general, the number of model evaluation required for an *OAT* design is of the order of $(2I + 1)$ model computations. Refinements, such as proposed in Kleijnen (1998), require only roughly half as many computations, while providing arguably more accurate estimators of the main effects.

Since classical *OAT* cannot provide information about interactions between parameters, the model's behavior can only be assessed in a relatively small interval around the "control" scenario. In other words, the classical *OAT* experiments yield information only about the system's response *local* behavior. Therefore, the results of a classical *OAT* experiment are meaningful only if the model's input-output relation can be adequately represented by a first order polynomial in the model's parameters. If the model is affected by nonlinearities (as is often the case in practice), then parameter changes around the "control" scenario would provide drastically different "sensitivities," depending on the chosen "control" scenario.

To address this severe limitation of the classical *OAT* designs, a *global OAT* design method has been proposed in Morris (1991), by covering the entire space in which the parameters may vary, independently of the specific initial "control" scenario one may commence the experiment with. A *global OAT* design assumes that the model is characterized by a large number of parameters and/or is computationally expensive (regarding computational time and computational resources) to run. The range of variation of each component of the vector α of parameters is standardized to the unit interval, and each component is then considered to take on p values in the set $\{0, (p - 1)^{-1}, 2(p - 1)^{-1}, \dots, 1\}$, so that the region of experimentation becomes an I -dimensional p -level grid. An *elementary effect* of the i th-parameter at a point α is then defined as $d_i(\alpha) \equiv [R(\alpha_1, \dots, \alpha_{i-1}, \alpha_i + \Delta, \alpha_{i+1}, \dots, \alpha_I) - R(\alpha)]/\Delta$, where Δ is a predetermined multiple of $1/(1 - p)$, such that $\alpha_i + \Delta$ is still within the region of experimentation. A finite distribution F_i of elementary effects for the i th-parameter is obtained by sampling α from within the region of experimentation. The number of elements for each F_i is $p^{k-1} [p - \Delta(p - 1)]$. The distribution F_i is then characterized by its mean and standard deviation. A high mean indicates a parameter with an important overall influence on the response; a high standard deviation indicates either a parameter interacting with other parameters or a parameter whose effect is nonlinear.

In its simplest form, the total computational effort required for a random sample of r values from each distribution F_i is $n = 2rI$; each elementary effect requires the evaluation of the response $R(\alpha)$ *twice*. For large-scale models, therefore, the *global OAT* design requires a relatively high computational effort, and can only provide a qualitative (but not quantitative) indication of the interactions of a parameter with the rest of the model. *OAT* cannot provide specific information about the identity of the interactions, and individual interactions among parameters cannot be estimated.

The *systematic fractional replicate design (SFRD)*, proposed in Cotter (1979), does not require any prior assumptions about interactions. For a model with I parameters, a *SFRD* involves the following steps: (1) one model computation with all parameters at their low levels; (2) I model computations with each parameter, in turn, at its upper level, while the remaining $(I - 1)$ parameters remain at their low levels; (3) I model computations with each parameter, in turn, at its low level, while the remaining $(I - 1)$ parameters remain at their upper levels; (4) one model computation with all parameters at their upper levels. Thus, a *SFRD* requires $2(I + 1)$ computations. Denoting by $(R_0, R_1, \dots, R_I, R_{I+1}, \dots, R_{2I}, R_{2I+1})$ the values of the responses computed in steps (1)–(4), the measures $M(j) \equiv |C_e(j)| + |C_o(j)|$, with $|C_e(j)| \equiv [(R_{2I+1} - R_{I+j}) - (R_j - R_0)]/4$ and $|C_o(j)| \equiv [(R_{2I+1} - R_{I+j}) + (R_j - R_0)]/4$, are used to estimate the order of importance of the I parameters α_i .

It is apparent from the above definitions that the measures $M(j)$ may fail when a parameter induces cancellation effects on the response, so that such a parameter would remain undetected by a *SFRD*. Worse yet, it is not possible to protect oneself a priori against such occurrences. Furthermore, a *SFRD* is not sufficiently precise, since the above definitions imply that, for one replicate, the variances would be $\text{var}[C_o(j)] = \text{var}[C_e(j)] = \sigma^2/4$, whereas a fractional replicate with n -computations would allow the estimations of parameter effects (on the response) with variances σ^2/n .

In addition to screening designs that consider each parameter individually, the (originally) individual parameters can be clustered into *groups* that are subsequently treated by *group screening designs*. Perhaps the most efficient modern group screening designs techniques are the *iterated fractional factorial design (IFFD)* proposed in Andres and Hajas (1993) and the *sequential bifurcation (SB)* technique proposed in Bettonvil (1990). In principle, the *IFFD* requires fewer model computations, n , than there are parameters, I . To identify an influential parameter, an *IFFD* investigates the groups through a fractional factorial design; the procedure is then repeated with different random groupings. Influential parameters are then sought at the intersection of influential groups. The *IFFD* samples three levels per parameter, designated low, middle, and high, while ensuring that the sampling is balanced: different combinations of values for two or three parameters appear with equal frequency. Hence, *IFFD* can be considered as a composite design consisting of multiple iterations of a basic *FFD*.

The *sequential bifurcation (SB)* design combines two design techniques, namely: (1) the *sequential design*, in which the parameter combinations are selected based on the results of preceding computations, and (2) *bifurcation*, in which each group that seems to include one or more important parameters is split into two subgroups of the same size. However, the *SB* design must *a priori* assume that the analyst knows the *signs* of the effects of the individual parameter, in order to ensure that effects of parameters assigned to the same group do not cancel out. Furthermore, the sequential nature of *SB* implies a more cumbersome data handling and analysis process than other screening design methods. To assess the effects of interactions between parameters, the number of *SB* computations becomes the double of the number of computations required to estimate solely the “main effects”; in particular, quadratic effects cannot be currently analyzed with the *SB* design technique, because of prohibitive computational requirements.

The screening designs surveyed in the foregoing are the most representative and the widest used methods aimed at identifying at the outset, in the initial phase of sensitivity and uncertainty analysis, the (hopefully not too many!) important parameters in a model. Each type of design has its own advantages and disadvantages, which can be summarized as follows: the advantages of *OAT* designs are: (1) no assumption of a monotonic input–output relation; (2) no assumption that the model contains only “a few” important parameters; and (3) the computational cost increases linearly with the number of parameters. The major disadvantage of *OAT* designs is the neglect of parameter interactions. Although such an assumption drastically simplifies the analysis of the model, it can rarely be accepted in practice. This simplifying assumption is absent in the *global OAT* design, which aims at determining the parameters that have (1) negligible effects, (2) linear and additive effects, and (3) nonlinear or interaction effects. Although the *global OAT* is easy to implement, it requires a high computational effort for large-scale models, and provides only a qualitative (but not quantitative) indication of the interactions of a parameter with the rest of the model; the *global OAT* cannot provide specific information about the identity of individual parameter interactions.

The *SFRD* does not require *a priori* assumptions about parameter interactions and/or about which few parameters are important. Although the *SFRD* is relatively efficient computationally,

it lacks precision and cannot detect parameters whose effects cancel each other out. The *IFFD* estimates the main and quadratic effects, and two-parameter interactions between the most influential parameters. Although the *IFFD* requires fewer computations than the total number of model parameters, the *IFFD* gives good results only if the model's response is actually influenced by only a few truly important parameters. The *SB* design is simple and relatively cost effective (computationally), but assumes that (1) the signs of the main effects are *a priori* known, and (2) the model under consideration is adequately described by two-parameter interactions.

3.3 Sampling-Based Methods

Consider that α denotes a vector of model parameters. If the uncertainty associated with α were known unambiguously, then the uncertainty in the response $R(u, \alpha)$ could also be assessed unambiguously. In practice, however, the uncertainty in α can rarely be specified unambiguously; most often, many possible values of α , of varying levels of plausibility, could be considered. Such uncertainties can be characterized by assigning a distribution of plausible values ($D_1, D_2, \dots, D_I$) to each component $\alpha_i(x)$ of α . Correlations and other restrictions can also be considered to affect the parameters $\alpha_i(x)$. Uncertainties characterized by such distributions are called *epistemic* or *subjective uncertainties*, and characterize a degree of belief regarding the location of the appropriate value of each $\alpha_i(x)$. In turn, these subjective uncertainties for the parameters $\alpha_i(x)$ lead to subjective uncertainties for the response $R(u, \alpha)$, which reflect a corresponding degree of belief regarding the location of the appropriate response values as the outcome of analyzing the model under consideration.

Sampling-based methods for sensitivity and uncertainty analysis are based on a sample

$$\alpha_k = [\alpha_{k1}, \alpha_{k2}, \dots, \alpha_{kI}], \quad (k = 1, 2, \dots, n_S), \quad (45)$$

of size n_S taken from the possible values of α as characterized by the distributions ($D_1, D_2, \dots, D_I$). The response evaluations corresponding to the sample α_k defined in (45) can be represented in vector form as

$$R(\alpha_k) = [R_1(\alpha_k), R_2(\alpha_k), \dots, R_J(\alpha_k)], \quad (k = 1, 2, \dots, n_S), \quad (46)$$

where the subscript J denotes the number of components of the response R . The pairs

$$[\alpha_k, R(\alpha_k)], \quad (k = 1, 2, \dots, n_S), \quad (47)$$

represent a mapping of the uncertain “inputs” α_k to the corresponding uncertain “outputs” $R(\alpha_k)$, which result from the “sampling-based uncertainty analysis.” Subsequent examination and post-processing (e.g., scatter plots, regression analysis, partial correlation analysis) of the mapping represented by (47) constitute procedures for “sampling-based sensitivity analysis,” in that such procedures provide means of investigating the effects of the elements of α on the elements of $R(u, \alpha)$. Thus, the “sampling-based uncertainty and sensitivity analysis” first commences with the “uncertainty analysis” stage, and only subsequently proceeds to the “sensitivity-analysis” stage, which is the exact reverse of the conceptual path underlying the methods of deterministic sensitivity and uncertainty analysis.

Specifically, a “sampling-based uncertainty and sensitivity analysis” involves five steps, as follows:

1. Define the subjective distributions $(D_1, D_2, \dots, D_I)$ for characterizing the uncertain input parameters;
2. Use the above distributions to generate the sample α_k described in (45);
3. Use each of the elements of the sample α_k in order to perform model recalculations, which then generate the responses $R(\alpha_k)$ described in (46);
4. Perform “uncertainty analysis” of the response $R(u, \alpha)$, by generating displays of the uncertainty in $R(u, \alpha)$ using the results for $R(\alpha_k)$ obtained above, in step 3;
5. Perform “sensitivity analysis” of the response $R(u, \alpha)$ to the parameters α , by exploring (using scatter plots, regression analysis, partial correlation analysis, etc.) the mappings represented by (47), to assess the effects of the components of α on the components of $R(u, \alpha)$.

Step 1: Of all of the above steps, the most important is the very first one, namely the definition of the distributions used to characterize subjective uncertainty. Because of its fundamental importance, the characterization of subjective uncertainty has been widely studied, for example, Berger (1985), Hora and Iman (1989), Bonano and Apostolakis (1991). In practice, this step invariably involves formal expert review processes. Although formal statistical procedures can be occasionally used for constructing subjective distributions, practical experience has shown that it is more useful to specify selected quantile (minimum, median, maximum, etc.) values, rather than attempt to specify a particular type of distribution (e.g., normal, beta, etc.) and its associated parameters. This is because the respective experts are more likely to be able to justify the selection of specific quantile values rather than the selection of a particular form of distribution with specific parameters. When distributions from several expert opinions are combined, it is practically very difficult to assign weights to the respective opinions; these difficulties are discussed, for example, in Clement and Winkler (1999).

Once a subjective distribution D_i has been assigned to each element $\alpha_i(x)$ of α , the collection of subjective distributions $(D_1, D_2, \dots, D_I)$ defines a probability space (S, E, p) , which is a formal structure where: (1) S denotes the sample space (containing everything that could occur in the particular universe under consideration; the elements of S are elementary events); (2) E denotes an appropriately restricted subspace of S , for which probabilities are defined; and (3) p denotes a probability measure.

Step 2: This step is to sample the probability space. The widest used sampling procedures are: random sampling, importance sampling, and Latin Hypercube sampling; the salient features of these procedures will be summarized briefly in the following. Thus, random sampling involves selection of the observations

$$\alpha_k = [\alpha_{k1}, \alpha_{k2}, \dots, \alpha_{kI}], \quad (k = 1, 2, \dots, n_{RS}), \quad (48)$$

where n_{RS} represents the sample size, according to the joint probability distribution for the elements of α as defined by (S, E, p) . A point from a specific region of S occurs as dictated by the probability of occurrence of the respective region. Moreover, each sample point is selected independently of all other sample points. Note, however, that there is no guarantee that points will be sampled from any given subregion of S . Furthermore, if sampled values fall closely

together, the sampling of S is quite inefficient. To address and alleviate these shortcomings, the so-called *importance sampling* procedure has been developed by dividing S exhaustively into several nonoverlapping subregions, referred to as *strata* S_i , ($i = 1, 2, \dots, n_S$). Thus, n_{S_i} values for α are sampled randomly from S_i , and the resultant vectors

$$\alpha_k = [\alpha_{k1}, \alpha_{k2}, \dots, \alpha_{kI}], \quad \left(k = 1, 2, \dots, \sum_{i=1}^{n_S} n_{S_i} \right), \quad (49)$$

form a sample obtained by importance-sampling, since the strata S_i are defined on the basis of how important the parameters $\alpha \in S_i$ (i.e., parameters that are contained in the strata) are to the final outcome of the analysis. Typically, only one value is sampled from each S_i , in which case (49) reduces to (45). Importance sampling is used to ensure that specified regions in the sample space are fully covered, thereby ensuring, in particular, that parameters which have low occurrence probabilities but high consequences are included in the analysis. The idea of fully covering the range of each parameter is further extended in the *Latin Hypercube sampling* procedure (see, for example, McKay et al. 1979). In this procedure, the range of each parameter α_i is divided into n_{LH} intervals of equal probability, and one value is randomly selected from each interval. The n_{LH} values thus obtained for the first parameter, α_1 , are then randomly paired, without replacement, with the n_{LH} values obtained for α_2 . In turn, these pairs are combined randomly, without replacement, with the n_{LH} values for α_3 to form n_{LH} triples. This process is continued until a set of $n_{LH}I$ -tuples are obtained, of the form

$$\alpha_k = [\alpha_{k1}, \alpha_{k2}, \dots, \alpha_{kI}], \quad (k = 1, 2, \dots, n_{LH}), \quad (50)$$

which is called a Latin Hypercube sample. This method is suited for uncorrelated parameters only; if the parameters are correlated, then the respective correlation structure must be incorporated into the sample, for otherwise the ensuing uncertainty/sensitivity analysis would yield false results. To incorporate parameter correlations into the sample, a restricted pairing technique for generating Latin Hypercubes was proposed (Iman and Conover 1982) based on rank correlations (i.e., correlations between rank-transformed parameters) rather than sample correlations (i.e., correlations between the original, untransformed, parameters).

Since random sampling is easy to implement and provides unbiased estimates for the means, variances, and distribution functions, it is the preferred statistical technique in practice, if large samples are available. However, a sufficiently “large sample,” for producing meaningful results by random sampling, cannot be generated for complex models (with many parameters) and/or for estimating extremely high quantiles (e.g., the 0.99999 quantile), since the computation of the required sample becomes prohibitively expensive and impractical. In such cases, the random sampling method of choice becomes the stratified sampling method. The main difficulty for implementing stratified sampling lies with defining the strata and for calculating the probabilities for the respective strata, unless considerable *a priori* knowledge is already available for this purpose. For example, the fault and event trees used in risk assessment studies of nuclear power plants and other complex engineering facilities can be used as algorithms for defining stratified sampling procedures. Latin Hypercube sampling is used when very high quantiles need not be estimated, but the calculations needed for generating the “large sample” required for random sampling still remain prohibitively demanding computationally. This is often the case in practice when assessing the effects of subjective uncertainty in medium-sized problems (e.g., ca. 30 parameters), for which a 0.9–0.95 quantile would be adequate for indicating the location

of a likely outcome. For such problems, random sampling is still unfeasible computationally, but the unbiased means and distribution functions provided by the full stratification (i.e., each parameter is treated equally) of the Latin Hypercube sampling makes it the preferred alternative over the importance sampling, where the unequal strata probabilities produce results that are difficult to interpret (particularly for subsequent sensitivity analysis). In this sense, Latin Hypercube sampling provides a compromise importance sampling when *a priori* knowledge of the relationships between the sampled parameters and predicted responses is not available.

Step 3: Once the sample has been generated, its elements must be used to perform model recalculations, which then generate the responses $\mathbf{R}(\alpha_k)$ described by (46). These model recalculations can become the most expensive computational part of the entire uncertainty and sensitivity analysis and, if the model is complex, the model recalculations may severely limit the sample size and the other aspects of the overall analysis.

Step 4: It is customary to display the estimated expected value and the estimated variance of the response (as estimated from the sample size). However, these quantities may not be the most useful indicators about the response because information is always lost in the calculations of means and variances. In particular, the mean and variance are less useful for summarizing information about the distribution of subjective uncertainties; often, quantiles associated with the respective distribution provide a more meaningful locator for the quantity under consideration. Distribution functions (e.g., cumulative and/or complementary distribution functions, density functions) would, of course, provide the complete information that could be extracted from the sample under consideration.

Step 5: In the context of sampling-based methods, statistical sensitivity analysis (as opposed to deterministic sensitivity analysis) involves the exploration of the mapping represented by (47) to assess the effects of some, but not all, of the individual components of α on the response $\mathbf{R}(\alpha)$. This exploration includes examination of scatter plots, regression and stepwise regression analysis, correlation and partial correlation analysis, rank transformation, identification of nonmonotonic patterns, and identification of nonrandom patterns. The starting point of statistical sensitivity analysis is the generation of scatter plots, which are obtained by plotting the points

$$(\alpha_{kj}, R_k), \quad (k = 1, \dots, n_S), \quad (51)$$

for each element α_j of α for $(j = 1, \dots, I)$. The resulting I scatter plots are then examined to find possible relations between the response $\mathbf{R}(\alpha)$ and the elements α_j of α .

A more formal analysis of the parameter-to-response mapping represented by (47) is to perform regression analysis on a linear model between the predicted responses, $R_{\text{predicted}}$, and the input parameters α_j , of the form

$$R_{\text{predicted}} = b_0 + \sum_{j=1}^I b_j \alpha_j. \quad (52)$$

The calculated responses, R_k , are also formally expressed in terms of the actual parameter values, α_{kj} , used in the analysis, by means of a linear relationship of the form

$$R_k = b_0 + \sum_{j=1}^I b_j \alpha_{kj} + \varepsilon_k, \quad (k = 1, \dots, M), \quad (53)$$

where M denotes the actual number of calculations, and where $\varepsilon \equiv R_k - R_{\text{predicted}}$ denotes the error between the calculated and predicted value of the corresponding element of the response. The regression analysis commences by assuming that the unknown regression coefficients b_j can be determined by minimizing the sums of the squared errors $\sum_k (R_k - R_{\text{predicted}})^2 \equiv \sum_k \varepsilon^2$. The regression coefficients b_j can be used, along with other indicators computed during the regression analysis, to assess the importance of the individual parameters α_j with respect to the uncertainty in the response components. A measure of the extent to which the regression model can match the observed data is provided by the so-called *coefficient of multiple determination*, C^2 , defined by the following ratio:

$$C^2 \equiv S_{\text{reg}}/S_{\text{tot}}, \quad S_{\text{reg}} \equiv \sum_{k=1}^M (R_{k,\text{est}} - R_{\text{ave}})^2, \quad S_{\text{tot}} \equiv \sum_{k=1}^M (R_k - R_{\text{ave}})^2, \quad (54)$$

where $R_{k,\text{est}}$ denotes the estimate of R_k obtained from the regression model, while R_{ave} denotes the mean of the R_k 's. A value of C^2 close to unity indicates that the regression model accounts well for most of the uncertainties in the quantities R_k 's; conversely, a value of C^2 close to zero indicates that the regression model accounts poorly for the uncertainties in the R_k 's. In the important particular case when the sampling design matrix α_k is orthogonal, each coefficient b_j can be determined by means of the formula

$$b_j = \left(\sum_{k=1}^M \alpha_{kj} R_k \right) / \left(\sum_{k=1}^M \alpha_{kj}^2 \right), \quad (55)$$

which indicates that the addition or deletion of model parameters will not change the regression coefficients for the remaining parameters. Furthermore, when the sampling design matrix α_k is orthogonal, then the coefficient of multiple determinations (54) decomposes into the additive form $C^2 = \sum_{k=1}^M C_k^2$, where C_k^2 denotes the value of C^2 when regressing R solely on α_k . In other words, when the sampling design matrix α_k is orthogonal, C_k^2 represents the contribution of α_k to C^2 .

Other useful concepts in sampling-based uncertainty/sensitivity analysis are the sample correlation and partial correlation coefficients. The *sample correlation coefficient*, $\text{Corr}(\alpha, R)$, between a parameter α and R for a sequence of observations (α_k, R_k) , ($k = 1, \dots, M$), is defined as

$$\text{Corr}(\alpha, R) \equiv \frac{\sum_{k=1}^M (\alpha_k - \alpha_{\text{ave}})(R_k - R_{\text{ave}})}{\left[\sum_{k=1}^M (\alpha_k - \alpha_{\text{ave}})^2 \right]^{1/2} \left[\sum_{k=1}^M (R_k - R_{\text{ave}})^2 \right]^{1/2}}, \quad (56)$$

where α_{ave} and R_{ave} denote the corresponding sample average values. Thus, the correlation coefficient, $\text{Corr}(\alpha, R)$, provides a measure of the linear relationship between the elements α_j of α , and the response(s) $R(\alpha)$.

It is important to note that correlated variables introduce unstable regression coefficients b_j , in that the values of b_j become sensitive to the specific variables introduced into the regression model. In such situations, the regression coefficients of a regression model that includes all

of the parameters are likely to give misleading indications of parameter importance. If several input parameters are suspected (or known) to be highly correlated, it is usually recommended to transform the respective parameters so as to remove the correlations or, if this is not possible, to analyze the full model by using a sequence of regression models with all but one of the parameters removed, in turn. Furthermore, if the regression model is used to match the predictions associated with individual sample parameters rather than to match the trend displayed by the collective sample, then over-fitting of data may arise if parameters are arbitrarily forced into the regression model.

Stepwise regression analysis, which involves the use of a sequence of regression models, is often used when the model under investigation contains many parameters and a regression analysis involving all the variables simultaneously is impractical. The *first step* in a stepwise regression analysis is to use a regression model that includes the single specific parameter that has the largest correlation with the response. The *second step* is to use a regression model that involves two parameters, namely: (1) the single parameter from step 1, and (2) a second parameter, chosen to be that parameter, among the remaining ones, that has the largest impact on the uncertainty that has remained unaccounted for in step 1 (i.e., the parameter that has the largest correlation with the residual uncertainty in the response R). The *third step* is to use a regression model involving three parameters, namely, (1) the two parameters from step 2, and (2) a third parameter, chosen to be that parameter, among the remaining ones, that has the largest impact on the uncertainty that has remained unaccounted for in step 2 (i.e., the parameter that has the largest correlation with the residual uncertainty in the response R , after the impact of the most important two parameters has been accounted for). This stepwise process of constructing successively more comprehensive regression models by adding additional parameters, in the order of their importance in contributing to the uncertainty in the response, is continued until the addition of further parameters can no longer account meaningfully for the residual uncertainty in the response. Note that correlations among parameters may cause an already selected parameter to be dropped out from the next-level regression model, if the respective parameter fails to have a significant impact on the residual uncertainty in the response.

In a stepwise regression analysis, it is important to guard against over-fitting the data; this danger occurs if the individual observations rather than the overall trend are fitted. For example, it is possible to fit the data apparently “better” by using a higher-order polynomial than the order indicated by the overall trend, in which case a spurious regression model would be constructed, leading to poor subsequent predictions. To protect against over-fitting, the predicted error sum of squares is usually used as a measure of the adequacy of the regression model, and also as a criterion for stopping the step-wise construction of the hierarchical regression models. Furthermore, F -tests or t -tests are used to determine when a variable is no longer needed and can therefore be dropped from the regression model.

Since the regression relationships discussed so far are based on linear representations of the impact of parameters on the response, these regression models will perform poorly when the relationships between the parameters and the response are nonlinear. In such cases, the *rank transformation* may be used to improve the construction of the respective regression model. The conceptual framework underlying rank transformation involves simply replacing the parameters by their respective ranks, and then performing the customary regression analysis on the ranks rather than the corresponding parameters (Iman and Conover 1982; Saltelli and Sobol’ 1995). In such an analysis, if the number of observations is M , then the smallest value of each parameter is assigned rank 1, the next largest value is assigned rank 2, etc., until the largest value, which is assigned rank M ; if several parameters have the same values, then they are assigned

an averaged rank. The regression analysis is then performed by using the ranks as input/output parameters, as replacements for the actual parameter/response values. This replacement has the effect of replacing the linearized parameter/response relationships by rank-transformed monotonic input/output relationships in an otherwise conventional regression analysis. In practice, a regression analysis using the rank-transformed (instead of raw) data may yield better results, but only as long as the relationships between parameters and responses are monotonically non-linear. Otherwise, the rank transformation does not improve significantly the quality of the results produced by regression analysis.

Departures from monotonic trends can be sometimes identified by using F -tests for detecting common means, χ^2 -tests for detecting common medians, and the Kruskal–Wallis test for common locations (Kleijnen and Helton 1999); all of these tests are performed using scatter plots. Scatter plots can also be used to identify nonrandom patterns, by using χ^2 -tests for detecting statistical independence between parameters. However, if the parameters are not independent but are statistically correlated, then the magnitudes and even the signs of the regression coefficients b_j associated with the respective parameters may be erroneous, and therefore indicate incorrectly the effects of such parameters on the response.

3.4 Variance-Based Methods

Sampling-based methods use variance, among other indicators, as a measure of the importance of a parameter in contributing to the overall uncertainty in the response. The concept of variance as a measure of the importance of a parameter also underlies the conceptual foundation of three further methods for statistical uncertainty and sensitivity analysis, namely, the *correlation-ratio method* (including variants thereof), the *Fourier Amplitude Sensitivity Test (FAST)*, and *Sobol's method*. It is important to note that, in contrast to the sampling-based methods discussed in the previous section, the correlation-ratio, the FAST, and Sobol's methods do not make the a priori assumption that the input model parameters are linearly related to the model's response.

The importance of an input parameter α in contributing to the predictive uncertainty in a response R (output) can be assessed by considering the marginal probability distribution, $p_R(R)$, of R , which can be written in terms of the conditional probability distribution, $p_{R|\alpha}(R|\alpha)$, of R conditioned on α , as follows:

$$p_R(R) = \int p_{R|\alpha}(R|\alpha) p_\alpha(\alpha) d\alpha. \quad (57)$$

The above relation can be intuitively interpreted as follows: a parameter α is important if fixing its value would substantially reduce the conditional prediction variance relative to the marginal prediction variance. This interpretation indicates that various conditional variance ratios may be used as indicators of importance. Specifically, the methods based on correlation-ratios assume that the model simulating the system under investigation is of the form

$$R = E(R|\alpha) + \epsilon, \quad (58)$$

where α represents, as before, the set of I model parameters, and ϵ represents a vector of errors with the properties that $E(\epsilon) = 0$ and $\text{Var}[E(R|\alpha), \epsilon] = \text{known}$. Note, however, that ϵ is not taken into consideration in numerical experiments.

Recall that in a standard regression analysis, the expectation $E(R|\alpha)$ is a priori assumed to have the linear form $\sum_{k=1}^M \alpha_k b_k$, where the quantities b_k are the regression coefficients, determined by least-square fitting. By contrast, there are no assumptions in (58) regarding the specific mathematical form of the conditional expectation $E(R|\alpha)$.

Based on the model defined by (58), the prediction variance, $\text{Var}(R)$, of R can be written in the form

$$\text{Var}(R) = \text{Var}_\alpha [E(R|\alpha)] + E_\alpha (\text{Var}[R|\alpha]), \quad (59)$$

where

$$\begin{aligned} E(R|\alpha) &\equiv \int p_{R|\alpha}(R) R \, dR, \\ \text{Var}_\alpha [E(R|\alpha)] &\equiv \int [E(R|\alpha) - E(R)]^2 p_\alpha(\alpha) \, d\alpha, \\ E_\alpha (\text{Var}[R|\alpha]) &\equiv \int [R - E(R|\alpha)]^2 [p_{R|\alpha}(R) \, dR] p_\alpha(\alpha) \, d\alpha. \end{aligned}$$

The quantity $\text{Var}_\alpha [E(R|\alpha)]$ is the variance of the conditional expectation of R conditioned on α ; this quantity measures the importance of α , since it indicates how the constituent parts of $\text{Var}(R)$, given by (59), relate to α . More specifically, $\text{Var}_\alpha [E(R|\alpha)]$ measures the total variation in R in the sense that, as α varies, the variation in R would match the variation in $E(R|\alpha)$, if the second term in (59), that is, $E_\alpha (\text{Var}[R|\alpha])$, were small. Actually, the term $E_\alpha (\text{Var}[R|\alpha])$ is a residual term that measures the remaining variability in R due to other unobserved inputs or other unknown sources of variation when α is fixed.

The additive decomposition in (59) can be used to define “variance-based first-order sensitivity indices,” S_i and a “variance-based correlation ratio,” η^2 , as follows

$$S_i \equiv \frac{\text{Var}_\alpha [E(R|\alpha_i)]}{\text{Var}(R)} \quad \text{and} \quad \eta^2 \equiv \frac{\text{Var}_\alpha [E(R|\alpha)]}{\text{Var}(R)}. \quad (60)$$

Note that η^2 represents a measure of the magnitude of the variance of the conditional expectation relative to the prediction variance $\text{Var}(R)$, and can be evaluated (McKay 1995) using a Latin Hypercube sampling of size m with r replicates. However, such an evaluation is computationally very expensive, requiring $rm \times (I+1)$ model evaluations, where I represents the number of parameters in α . A somewhat more economical method for evaluating η^2 is the resampling-based method presented in Saltelli et al. (1993), which requires $n(I+1)$ model evaluations, where n represents the sample size for evaluating $E(R|\alpha_i)$ for a specified value of α_i , and where I represents the number of parameters in α .

The FAST procedure, originally proposed in Cukier et al. (1973), uses the following Fourier transformation of the parameters α_i :

$$\alpha_i = F_i \sin(\omega_i z), \quad i = 1, \dots, I, \quad (61)$$

where $\{\omega_i\}$ is a set of integer frequencies, while $z \in (-\pi, \pi)$ is a scalar variable. The expectation $E(R)$ and variance of the response R can be approximated as follows

$$E(R) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(z) \, dz, \quad \text{Var}(R) \approx 2 \sum_{j=1}^{\infty} (A_j^2 + B_j^2),$$

where

$$f(z) \equiv f[F_1 \sin(\omega_1 z), F_2 \sin(\omega_2 z), \dots, F_I \sin(\omega_I z)],$$

$$A_j \equiv \frac{1}{2\pi} \int_{-\pi}^{\pi} f(z) \cos(jz) dz, \quad B_j \equiv \frac{1}{2\pi} \int_{-\pi}^{\pi} f(z) \sin(jz) dz.$$

The transformation shown in (61) should provide, for each parameter α_i , a uniformly distributed sample in the unit I -dimensional cube. As $z \in (-\pi, \pi)$ varies for a given transformation, all parameters change simultaneously; however, their respective ranges of uncertainty is systematically and exhaustively explored (i.e., the search curve is space-filling) if and only if the set of frequencies $\{\omega_i\}$ is incommensurate (i.e., if none of the frequencies ω_i may be obtained as a linear combination, with integer coefficients, of the remaining frequencies).

The first-order sensitivity indices are computed by evaluating the coefficients A_j and B_j for the fundamental frequencies $\{\omega_i\}$ and their higher harmonics, $p\omega_i$ ($p = 1, 2, \dots$). If the frequencies $\{\omega_i\}$ are integers, the contribution to the total variance $\text{Var}(R)$ coming from the variance D_i corresponding to parameter α_i is approximately obtained as $D_i \cong 2 \sum_{p=1}^M (A_{p\omega_i}^2 + B_{p\omega_i}^2)$, where M is the maximum harmonic taken into consideration (usually $M \leq 6$). The ratio of the partial variance D_i to the total variance $\text{Var}(R)$ provides the so-called first-order sensitivity index. The minimum sample size required to compute D_i is $(2M\omega_{\max} + 1)$, where $\omega_{\max}$ is the maximum frequency in the set $\{\omega_i\}$. Furthermore, the frequencies that do not belong to the set $\{p_1\omega_1, p_2\omega_2, \dots, p_I\omega_I\}$ for $(p_i = 1, 2, \dots, \infty)$, and for any $(i = 1, 2, \dots, I)$, contain information about the residual variance $[\text{Var}(R) - D_i]$ that is not accounted for by the first-order indices. This residual variance can be computed in $(I \times N_S)$ computations, where N_S is the respective sample size.

A related class of variance-based methods has its roots in a theorem by Kolmogorov that states that any multivariate function, $f(x_1, x_2, \dots, x_n)$, defined in the unit n -dimensional cube $[0, 1]^n$, can be written as a linear superposition of univariate functions, $h_j(x_i)$, of the form

$$f(\mathbf{x}) \equiv f(x_1, x_2, \dots, x_n) = \sum_{j=1}^{2n+1} g[a_1 h_j(x_1) + a_2 h_j(x_2) + \dots + a_n h_j(x_n)], \quad (62)$$

where the functions $h_j(x_i)$ are continuous (but highly non-smooth). Although Kolmogorov's expansion shown in (62) is seldom used in practice for interpolation and/or approximation of multivariate functions, it has inspired the development of several (somewhat) more practical algorithms for representing multivariate functions, such as the projection pursuit algorithms (Stone 1985), multilayer perceptrons (Parker 1985), Sobol's method (Sobol' 1993), and ANOVA-like decompositions (Archer et al. 1997), which can also be used for uncertainty and sensitivity analysis.

Perhaps the most practical of the methods mentioned above is a method due to Sobol' (1993), in which the multivariate function $f(x_1, x_2, \dots, x_n)$ is decomposed into summands of increasing dimensionality of the form

$$f(x_1, x_2, \dots, x_n) = f_0 + \sum_{i=1}^n f_i(x_i) + \sum_{1 \leq i < j \leq n} f_{ij}(x_i, x_j) + \dots + f_{12\dots n}(x_1, x_2, \dots, x_n). \quad (63)$$

The decomposition in (63) is unique if the variables are uncorrelated, and has the following properties:

1. The integrals of any summand over any of its own variables is zero, that is,

$$\int_0^1 f_{i_1 i_2 \dots i_n} (x_{i_1}, x_{i_2}, \dots, x_{i_n}) dx_{i_m} = 0, \quad \text{if } 1 \leq m \leq n,$$
2. The summands are orthogonal, that is,

$$\int_{[0,1]^n} f_{i_1 i_2 \dots i_n} f_{j_1 j_2 \dots j_m} dx = 0 \quad \text{if } (i_1, i_2, \dots, i_n) \neq (j_1, j_2, \dots, j_m);$$

3. f_0 is a constant, that is, $f_0 = \int_{[0,1]^n} f(\mathbf{x}) d\mathbf{x}$.

By squaring (63) and integrating the resulting expression over the unit cube $[0,1]^n$, the following relation is obtained for the total variance D of $f(\mathbf{x})$:

$$D \equiv \int_{[0,1]^n} f^2(\mathbf{x}) d\mathbf{x} - f_0^2 = \sum_{i=1}^n D_i + \sum_{1 \leq i < j \leq n} D_{ij} + \dots + D_{12\dots n}, \quad (64)$$

where the partial variances of $f(\mathbf{x})$ are defined as

$$D_{i_1 i_2 \dots i_m} = \int_0^1 \dots \int_0^1 f_{i_1 i_2 \dots i_m} (x_{i_1}, x_{i_2}, \dots, x_{i_m}) dx_{i_1} \dots dx_{i_m}, \quad (65)$$

for $1 \leq i_1 < \dots < i_m \leq n, m = 1, \dots, n$.

The sensitivity indices are defined as

$$S_{i_1 i_2 \dots i_m} \equiv D_{i_1 i_2 \dots i_m} / D, \quad \text{for } 1 \leq i_1 < \dots < i_m \leq n, m = 1, \dots, n. \quad (66)$$

The *first-order sensitivity index*, S_i , for the parameter x_i indicates the fractional contribution of x_i to the variance D of $f(\mathbf{x})$; the *second-order sensitivity index*, S_{ij} , ($i \neq j$), measures the part of the variation in $f(\mathbf{x})$ due to x_i and x_j that cannot be explained by the sum of the individual effects of x_i and x_j ; and so on. Note also that (65) and (66) imply that

$$\sum_{i=1}^n S_i + \sum_{i < j \leq n} S_{ij} + \dots + S_{12\dots n} = 1. \quad (67)$$

4 Deterministic Computation of Response Sensitivities to Parameters Using Adjoint Operators

4.1 Introduction

The mathematical model of a physical system usually comprises: (1) linear and/or nonlinear equations that relate the system's independent variables and parameters to the system's state (i.e.,

dependent) variables, (2) probability distributions and/or constraints that define the domains and properties of the system's parameters, and (3) one or several quantities, customarily referred to as system responses (or objective functions, or indices of performance) that are to be analyzed as the parameters vary over their respective domains.

In large-scale, complex models, the importance of parameters is not a priori obvious, and may often be counterintuitive. To analyze such complex models, information about the slopes of the model's response at a given set of nominal parameter values in parameter space is of paramount importance. The exact slopes are provided by the local partial functional derivatives $\partial R/\partial \alpha_i$ of the response R with respect to the model parameters α_i . These local partial functional derivatives are called the *local sensitivities* of the model's response to parameter variations. The objective of *local sensitivity analysis* is to analyze the behavior of the system responses locally around a chosen point or trajectory in the combined phase space of parameters and state variables. On the other hand, the objective of *global sensitivity analysis* is to determine all of the system's critical points (bifurcations, turning points, response extrema) in the combined phase space formed by the parameters, state variables, and adjoint variables, and subsequently analyze these critical points by local sensitivity analysis.

The simplest way of estimating local sensitivities is by *recalculations* of the model's response, using parameter values that deviate by small amounts, $\delta \alpha_i$, of the order of 1%, from their nominal values α_i^0 . The sensitivities are then estimated by using a finite difference approximation to $\partial R/\partial \alpha_i$ of the form

$$\left\{ \frac{\partial R}{\partial \alpha_i} \right\}_{\alpha^0} = \frac{R(\alpha_1^0, \dots, \alpha_i^0 + \delta \alpha_i, \dots, \alpha_I^0) - R(\alpha_i^0)}{\delta \alpha_i}, \quad (i = 1, \dots, I).$$

This procedure, occasionally called the “*brute-force method*,” requires $(I + 1)$ model computations; if central differences are used, the number of model computations could increase up to a total of $2I$. Although this method is conceptually simple to use and requires no additional model development, it is slow, relatively expensive computationally, and involves a trial-and-error process when selecting the parameter perturbations $\delta \alpha_i$. Note that *erroneous sensitivities will be obtained if*: (1) $\delta \alpha_i$ is chosen to be too small, in which case the computational round-off errors may overwhelm the correct values, and (2) *the parameter dependence is nonlinear and $\delta \alpha_i$ is chosen too large*, in which case the assumption of local linearity is violated.

Local sensitivities can be computed exactly only by using deterministic methods that involve some form of differentiation of the system under investigation. The (comparatively few) deterministic methods for calculating sensitivities exactly are as follows: the *direct method* (including its *decoupled direct method* variant), the *Green's function method*, the *forward sensitivity analysis procedure* (FSAP), and the *adjoint sensitivity analysis procedure* (ASAP). The so-called *direct method* has been applied predominantly to systems involving differential and/or algebraic equations describing chemical kinetics (including combustion kinetics) and molecular dynamics. This method involves differentiation of the system of equations underlying the model with respect to each parameter in the model. The sensitivity to each parameter is then computed by solving the respective differentiated system. The most advanced and computationally economical version of the direct method is the *decoupled direct method* (DDM), introduced in Dunker (1984), in which the Jacobian matrix needed to solve the original system at a given time-step is also used to solve the sensitivity equations at the respective time-step, before proceeding to

solve both the original and sensitivity systems at the next time-step. Note that the computational effort increases linearly with the number of parameters.

Another method occasionally used for computing sensitivities for models governed by first-order derivatives in time is the *Green function method* (*GFM*). This method commences by differentiating the underlying model with respect to its initial conditions to obtain a Green's function, which is subsequently convoluted with the matrix of parameter derivatives, and is finally integrated in time to obtain the respective time-dependent sensitivities. There are several variants of the *GFM*; the integrated Magnus version (*GFM/AIM*) proposed in Kramer et al. (1981) appears to be, the most efficient *GFM* computationally. In practice, though, the *GFM* is seldom used, since it is computationally more expensive and considerably more difficult to implement than the *DDM*.

As introduced in Cacuci (1981a, b), the most general and comprehensive way of defining *local* sensitivities for general operators (in the sense of nonlinear functional analysis) is in terms of the first *Gâteaux-differential* of the system's response, computed at the respective nominal value of the system's dependent variables and parameters. Two procedures have been developed in Cacuci (1981a, b) based on the concept of *Gâteaux-differentials*, for computing the local sensitivities for any type of response, namely: the *forward sensitivity analysis procedure* (*FSAP*) and the *adjoint sensitivity analysis procedure* (*ASAP*). The *FSAP* constitutes a generalization of the *decoupled direct method* (*DDM*), since the concept of *Gâteaux-differential* (which underlies the *FSAP*) constitutes the generalization of the concept of total-differential in the calculus sense, which underlies the *DDM*. Notably, the *Gâteaux-differential* exists for operators and generalized functions (e.g., distributions) that are not continuous in the ordinary calculus-sense, and therefore do not admit the “nice” derivatives required for using the *DDM*. As expected, the *FSAP* reduces to the *DDM*, whenever the continuity assumptions required by the *DDM* are satisfied. Finally, even though the *FSAP* represents a generalization of the *DDM*, the *FSAP* requires the *same* computational and programming effort to develop and implement as the *DDM*. Hence, just as the *DDM*, the *FSAP* is advantageous to employ only if the number of different responses of interest for the problem under consideration exceeds the number of system parameters and/or parameter variations to be considered. Otherwise, the use of either the *FSAP* or the *DDM* becomes impractical for large systems with many parameters, because of the very large demand on computational resources.

For large-scale systems, in which the number of system parameters and/or parameter variations to be considered exceeds the number of responses of interest, the *ASAP* is, by far, the most advantageous method to employ, even though it can only be implemented if an appropriately constructed adjoint sensitivity system is already available. The remarkable efficiency of the *ASAP* stems from the fact that the adjoint sensitivity system is linear in the adjoint function, and is independent of any parameter variations. Hence, the adjoint sensitivity equation needs to be solved only once, for each response, in order to obtain the adjoint function. In particular, if the original model is linear in the state (i.e., dependent) variables, then the adjoint sensitivity equation can be solved independently of the original model. In turn, once the adjoint function has been calculated, it is used to obtain the sensitivities to all system parameters, by simple quadratures, without needing to solve repeatedly differential and/or integral equations. Thus, for the large-scale systems, with many parameters, as usually encountered in practice, the *ASAP* is the most efficient method to use for sensitivity analysis. The general mathematical framework for deriving both the *FSAP* and *ASAP* for nonlinear systems with feedback and operator-type responses will be presented in ➤ Sect. 4.2, in the sequel.

Since the operations of discretization and Gâteaux-differentiation do not commute, there are two distinct paths that can be pursued for computing sensitivities, namely:

- (a) first apply the *FSAP* and *ASAP* to differential and/or integral equations, then discretize the resulting Forward and/or Adjoint Sensitivity Equations, and finally solve the resulting algebraic equations numerically; or
- (b) first discretize the original (linear and/or nonlinear) differential and/or integral equations, then apply the *FSAP* and *ASAP* to the resulting linear and/or nonlinear algebraic equations, and finally solve the resulting algebraic equations numerically. These procedures were first developed in Cacuci (2003) and Cacuci et al. (2005) under the names *discrete forward sensitivity analysis procedure (DFSAP)* and *discrete adjoint sensitivity analysis procedure (DASAP)*, respectively.

The algebraic equations resulting from following path (a) will be different from the algebraic equations resulting from path (b), because the two paths will, in general, produce different truncation errors. Thus, it is very useful, both theoretically and in practice, to distinguish between the procedures underlying path (a) and those underlying path (b), respectively. Of course, it is paramount to ensure that both paths yield consistent discretizations, since they both should constitute discretization of the same adjoint sensitivity equations. These important issues are discussed in detail in Cacuci (2003) and Cacuci et al. (2005).

As mentioned in ► Sect. 3, the exact local sensitivities obtained by using deterministic methods can be used for the following purposes: (1) understand the system by highlighting important data; (2) eliminate unimportant data; (3) determine effects of parameter variations on system behavior; (4) design and optimize the system (e.g., maximize availability/minimize maintenance); (5) reduce over-design; (6) prioritize the improvements effected in the respective system; (7) prioritize introduction of data uncertainties; and (8) perform local uncertainty analysis by using the “propagation of errors” method.

Large-scale simulation models have been historically developed without simultaneously implementing the corresponding adjoint sensitivity models. Implementing *a posteriori* the *ASAP* for large-scale simulation codes is not a trivial task, and the development and implementation of the adjoint sensitivity model for an entire large-scale code system can seldom be executed all at once. Hence, the recommended strategy for building the adjoint sensitivity system for a large-scale simulation code is a module-by-module implementation of the *ASAP* to each simulation module. In the final step of such a “modular” implementation of the *ASAP*, the adjoint sensitivity systems for each of the respective modules is “augmented,” without redundant effort and/or loss of information, until all adjoint modules are judiciously connected together, accounting for all of the requisite feedbacks and liaisons between the respective adjoint modules. ► Section 4.3 presents the theoretical foundation for the modular implementation of the *ASAP* for a complex simulation system, by starting with a selected code module, and then augmenting the size of the adjoint sensitivity system, module by module, until completing the entire system under consideration. This presentation closely follows the original derivations in Cacuci and Ionescu-Bujor (2005) and Ionescu-Bujor et al. (2005).

As an illustrative application of the *ASAP* to a large scale system, ► Sect. 4.4 presents a paradigm adjoint sensitivity analysis of dynamic reliability models based on Markov chains, following the novel work presented in Cacuci and Ionescu-Bujor (2008) and Cacuci et al. (2008). This novel application of the *ASAP* is relatively easy to follow, and has large applicability since Markov chains are used extensively to analyze and predict system reliability and availability in many branches of industry (e.g., cell phones, computers, communication and networks,

health equipment, aviation and aerospace, automotive engineering, chemical processing, military application, nuclear engineering), economic/econometric models, population forecasting, biology, and even financial planning. Other applications of ASAP can be found in the references listed at the end of this chapter.

The earliest attempts at extending the region of validity of local sensitivities beyond first-order were focused on computing second- and higher-order response derivatives with respect to the system's parameters. However, the number of equations that would need to be solved for obtaining the second- (and higher-) order derivatives of the response is very large, and depends on the number of parameter variations. For this reason, none of the deterministic techniques (proposed in the literature thus far) for computing second- and higher-order response derivatives with respect to the system's parameters has proven routinely practicable for large-scale problems. In particular, the computation of the second-order derivatives of the response and system's equations is already as difficult as undertaking the complete task of computing the exact value of perturbed response. Furthermore, since the Taylor series is a local concept, valid within some radius of convergence of the respective series around the nominal parameter values, it follows that even if the response derivatives were available to all orders, they would still merely provide local, but not global, information. Thus, they would yield little, if any, information about the important global features of the physical system, namely, the critical points of the response and the bifurcation branches and/or turning points of the system's state variables.

Instead of computing higher order response derivatives, the so-called *feature sensitivity analysis* for nonlinear probing of a larger region in the parameter-space has been proposed in Kramer et al. (1984), but the applications thus far have been limited to illustrative applications. A genuinely global deterministic method for sensitivity analysis, called the *global adjoint sensitivity analysis procedure* (GASAP), has been developed in Cacuci (1990). The GASAP uses both the forward and the adjoint sensitivity system to explore, exhaustively and efficiently, the entire phase-space of system parameters and dependent variables, in order to obtain complete information about the critical points of the response and the bifurcation branches and/or turning points of the system's state variables. The GASAP and the "feature sensitivity analysis" methods will be discussed in ► Sect. 4.5.

4.2 Sensitivity Analysis of Nonlinear and Linear Systems with Feedback and Operator-Type Responses

The physical system considered in this chapter is modeled mathematically by means of K coupled nonlinear equations represented in operator form as

$$N[u(x), \alpha(x)] = Q[\alpha(x)], \quad x \in \Omega, \quad (68)$$

where

1. $x = (x_1, \dots, x_J)$ denotes the phase-space position vector; $x \in \Omega \subset \mathbb{R}^J$, where Ω is a subset of the J -dimensional real vector space $\mathbb{R}^J$;
2. $u(x) = [u_1(x), \dots, u_K(x)]$ denotes the vector of dependent (i.e., state) variables; $u(x) \in E_u$, where E_u is a normed linear space over the scalar field F of real numbers;
3. $\alpha(x) = [\alpha_1(x), \dots, \alpha_I(x)]$ denotes the vector of system parameters; $\alpha \in E_\alpha$, where E_α is also a normed linear space; in usual applications, E_α may be one of the Hilbert spaces L_2

or l_2 ; occasionally, the components of α may simply be a set of real scalars, in which case E_α is $\mathbb{R}^I$;

4. $\mathbf{Q}[\alpha(\mathbf{x})] = [\mathbf{Q}_1(\alpha), \dots, \mathbf{Q}_K(\alpha)]$ denotes a (column) vector whose elements represent inhomogeneous source terms that depend either linearly or nonlinearly on α ; $\mathbf{Q} \in E_Q$, where E_Q is again a normed linear space; the components of $\mathbf{Q}$ may be operators (rather than just functions) acting on $\alpha(\mathbf{x})$ and $\mathbf{x}$;
5. $\mathbf{N} \equiv [N_1(\mathbf{u}, \alpha), \dots, N_K(\mathbf{u}, \alpha)]$ is a K -component column vector whose components are, in general, *nonlinear* operators (including differential, difference, integral, distributions, and/or infinite matrices) of $\mathbf{u}$ and α .

In view of the definitions given above, $\mathbf{N}$ represents the mapping $\mathbf{N} : D \subset E \rightarrow E_Q$, where $D = D_u \times D_\alpha$, $D_u \subset E_u$, $D_\alpha \subset E_\alpha$, and $E = E_u \times E_\alpha$. Note that an arbitrary element $\mathbf{e} \in E$ is of the form $\mathbf{e} = (\mathbf{u}, \alpha)$. Even though in most practical applications E and E_Q will be Hilbert spaces (e.g., the space L_2 , the Sobolev spaces H^m), this restriction is not imposed at this stage for the sake of generality. If differential operators appear in (68), then a corresponding set of boundary and/or initial conditions (which are essential to define D) must also be given. The respective boundary conditions are represented as

$$[\mathbf{B}(\mathbf{u}, \alpha) - \mathbf{A}(\alpha)]_{\partial\Omega} = 0, \quad \mathbf{x} \in \partial\Omega, \quad (69)$$

where $\mathbf{A}$ and $\mathbf{B}$ are nonlinear operators while $\partial\Omega$ is the boundary of Ω .

The vector-valued function $\mathbf{u}(\mathbf{x})$ is considered to be the unique nontrivial solution of the physical problem described by (68) and (69). The system response (i.e., performance parameter) $\mathbf{R}(\mathbf{u}, \alpha)$ associated with the problem modeled by (68) and (69) is a phase-space dependent mapping that acts nonlinearly on the system's state vector $\mathbf{u}$ and parameters α , and is represented in operator form as

$$\mathbf{R}(\mathbf{e}) : D_R \subset E \rightarrow E_R, \quad (70)$$

where E_R is a normed vector space.

The nominal parameter values $\alpha^0(\mathbf{x})$ are used in (68) and (69) to obtain the nominal solution $\mathbf{u}^0(\mathbf{x})$ by solving

$$\mathbf{N}(\mathbf{u}^0, \alpha^0) = \mathbf{Q}(\alpha^0), \quad \mathbf{x} \in \Omega, \quad (71)$$

$$\mathbf{B}(\mathbf{u}^0, \alpha^0) = \mathbf{A}(\alpha^0), \quad \mathbf{x} \in \partial\Omega. \quad (72)$$

Once the nominal values $\mathbf{u}^0(\mathbf{x})$ have been obtained by solving the above equations, they are used together with the nominal parameter values $\alpha^0(\mathbf{x})$ in (70) to obtain the nominal response value $\mathbf{R}(\mathbf{u}^0, \alpha^0)$.

Feedback is introduced into the model by allowing some (or all) of the parameters α to depend on some (or all) of the components of $\mathbf{u}$. Without loss of generality, a feedback mechanism can be specified by adding an operator, $\mathbf{F}(\mathbf{u})$, to the nominal parameter values α^0 . Thus, in the presence of feedback, the values of the parameters become $\alpha^0 + \mathbf{F}(\mathbf{u})$; correspondingly, the solution $\mathbf{u}^f$ of the system with feedback will satisfy the equations

$$\mathbf{N}[\mathbf{u}^f, \alpha^0 + \mathbf{F}(\mathbf{u}^f)] = \mathbf{Q}[\alpha^0 + \mathbf{F}(\mathbf{u}^f)], \quad \mathbf{x} \in \Omega, \quad (73)$$

$$\mathbf{B}[\mathbf{u}^f, \alpha^0 + \mathbf{F}(\mathbf{u}^f)] = \mathbf{A}[\alpha^0 + \mathbf{F}(\mathbf{u}^f)], \quad \mathbf{x} \in \partial\Omega. \quad (74)$$

The system response with feedback becomes $R[u^f, \alpha^0 + F(u^f)]$. The difference

$$R[u^f, \alpha^0 + F(u^f)] - R(u^0, \alpha^0), \quad x \in R, \quad (75)$$

gives the actual effect of the feedback F on the response $R(u^0, \alpha^0)$, and can be calculated exactly only by solving (73) and (74) anew for each F , and then using the respective solution u^f to evaluate $R[u^f, \alpha^0 + F(u^f)]$.

The sensitivity, DR_F , of the response with feedback, $R[u^f, \alpha^0 + F(u^f)]$, to parameters and feedback variations around the nominal response value $R(u^0, \alpha^0)$ is given by the Gâteaux-differential

$$DR_F \equiv \left\{ \frac{d}{d\varepsilon} R[u^0 + \varepsilon h, \alpha^0 + \varepsilon F(u^0 + \varepsilon h)] \right\}_{\varepsilon=0}, \quad (76)$$

where $h \equiv u^f - u$. For most practical applications, performing the operations indicated in (76) gives

$$DR_F = R'_1(u^0, \alpha^0)h + R'_2(u^0, \alpha^0)F(u^0), \quad x \in \Omega_R, \quad (77)$$

where R'_1 and R'_2 denote, respectively, the Gâteaux-derivatives of $R(u, \alpha)$ with respect to its first and second arguments. Customarily, the second term on the right-side of (77) can be calculated directly, with little effort, since it does not depend on h ; therefore, this term is usually called the “direct effect” term. However, the first term on the right-side of (77) can only be computed after having determined the variational vector on h ; hence, this term is called the “indirect-effect” term, since it contributes to the sensitivity DR_F through h .

4.2.1 The Forward Sensitivity Analysis Procedure (FSAP)

The vector of variations, $h \equiv u^f - u$, is needed in order to compute the sensitivity DR_F obtained in (77) above. To first order variations in the feedback and/or parameters, the variations $h \equiv u^f - u$ are obtained by solving the equations obtained by taking the Gâteaux-differentials of (73) and (76) at (u^0, α^0) , namely

$$N'_1(u^0, \alpha^0)h = [Q'(\alpha^0) - N'_2(u^0, \alpha^0)]F(u^0), \quad x \in \Omega, \quad (78)$$

$$B'_1(u^0, \alpha^0)h = [A'(\alpha^0) - B'_2(u^0, \alpha^0)]F(u^0), \quad x \in \partial\Omega. \quad (79)$$

Equations (78) and (79) are called the *forward sensitivity equations*, or the *forward variational tangent model*. In principle, the sensitivity DR_F can be evaluated once (78) and (79) have been solved to determine h . However, these equations would have to be solved anew for each F , and this becomes prohibitively expensive if many effects of all possible feedback and parameter variations are to be analyzed.

4.2.2 Adjoint (Local) Sensitivity Analysis Procedure (ASAP)

The *Adjoint Sensitivity Analysis Procedure* (ASAP) is the alternative method for calculating the sensitivity DR_F , and the ASAP circumvents the need for repeatedly solving (78) and (79). To

begin with, we note that the second term on the right-side of (77) can be calculated directly, with little effort, since it does not depend on $\mathbf{h}$ (this is the so-called “direct effect” term). To calculate the first term on the right-side of (77), that is, the “indirect-effect” term, the spaces E_u , E_Q , and E_R are henceforth considered to be Hilbert spaces and denoted as $H_u(\Omega)$, $H_Q(\Omega)$, and $H_R(\Omega_R)$, respectively. The elements of $H_u(\Omega)$ and $H_Q(\Omega)$ are, as before, vector functions defined on the open set $\Omega \subset \mathbb{R}^J$, with a smooth boundary $\partial\Omega$. The elements of $H_R(\Omega_R)$ are vector- or scalar-valued functions defined on the open set $\Omega_R \subset \mathbb{R}^m$, $1 \leq m \leq J$, with a smooth boundary $\partial\Omega_R$. Of course, if $J = 1$, then $\partial\Omega$ merely consists of two endpoints; similarly, if $m = 1$, then $\partial\Omega_R$ consists of two endpoints only. The inner products on $H_u(\Omega)$, $H_Q(\Omega)$, and $H_R(\Omega_R)$ are denoted by $\langle \bullet, \bullet \rangle_u$, $\langle \bullet, \bullet \rangle_Q$, and $\langle \bullet, \bullet \rangle_R$, respectively.

Since $\mathbf{R}'_1(\mathbf{u}^0, \boldsymbol{\alpha}^0) \mathbf{h} \in H_R(\Omega_R)$, it follows that

$$\mathbf{R}'_1(\mathbf{u}^0, \boldsymbol{\alpha}^0) \mathbf{h} = \sum_{s \in S} \langle \mathbf{p}_s, \mathbf{R}'_1 \mathbf{h} \rangle_R \mathbf{p}_s, \quad (80)$$

where $\mathbf{p}_s$ is an orthonormal basis for $H_R(\Omega_R)$, $\langle \cdot, \cdot \rangle_R$ denotes the inner product in H_R , and the series $\sum_{s \in S}$ converges unconditionally over the nonzero elements in S (which could be infinitely many).

The functionals $\langle \mathbf{p}_s, \mathbf{R}'_1 \mathbf{h} \rangle_R$ are the Fourier coefficients of $\mathbf{R}'_1 \mathbf{h}$ with respect to the basis $\mathbf{p}_s$. In practice, the basis $\mathbf{p}_s$ is often chosen to be a set of orthogonal polynomials, particularly Chebyshev polynomials. Note that since the operator $\mathbf{R}'_1 \mathbf{h}$ is linear in $\mathbf{h}$, the functionals $\langle \mathbf{p}_s, \mathbf{R}'_1 \mathbf{h} \rangle_R$ are also linear in $\mathbf{h}$. Furthermore, since $\mathbf{R}'_1 \mathbf{h} \in L(H_u(\Omega), H_R(\Omega_R))$ and since Hilbert spaces are self-dual, it follows that $\mathbf{R}'_1(\mathbf{u}^0, \boldsymbol{\alpha}^0)$ admits a unique adjoint operator, denoted here as the linear operator $\mathbf{M}(\mathbf{u}^0, \boldsymbol{\alpha}^0) \in L(H_R(\Omega_R), H_u(\Omega))$, and defined, as customary, in terms of inner products by means of the relationship:

$$\langle \mathbf{p}_s, \mathbf{R}'_1(\mathbf{u}^0, \boldsymbol{\alpha}^0) \mathbf{h} \rangle_R = \langle \mathbf{M}(\mathbf{u}^0, \boldsymbol{\alpha}^0) \mathbf{p}_s, \mathbf{h} \rangle_u, \quad \text{for every } s \in S. \quad (81)$$

Equations (78) and (79) reveal that the Gâteaux-derivatives $\mathbf{N}'_1 \mathbf{h}$ and $\mathbf{B}'_1 \mathbf{h}$ are linear in $\mathbf{h}$. It is therefore possible to introduce, for every vector $\boldsymbol{\psi}_s \in H_Q(\Omega)$, the operator adjoint to $\mathbf{N}'_1 \mathbf{h}$, by means of the relation

$$\langle \boldsymbol{\psi}_s, \mathbf{N}'_1(\mathbf{u}^0, \boldsymbol{\alpha}^0) \mathbf{h} \rangle_Q = \langle \mathbf{L}^+(\mathbf{u}^0, \boldsymbol{\alpha}^0) \boldsymbol{\psi}_s, \mathbf{h} \rangle_u + \{ \mathbf{P}(\mathbf{h}, \boldsymbol{\psi}_s) \}_{\partial\Omega}, \quad s \in S, \quad (82)$$

where the $K \times K$ matrix $\mathbf{L}^+ = [L^+_{ji}]$, $(i, j = 1, \dots, K)$, obtained by transposing the formal adjoints L^+_{ij} of the operators $(\mathbf{N}'_1)_{ij}$, is the formal adjoint of $\mathbf{N}'_1(\mathbf{u}^0, \boldsymbol{\alpha}^0)$, while $\{ \mathbf{P}(\mathbf{h}, \boldsymbol{\psi}_s) \}_{\partial\Omega}$ represents the associated bilinear form (concomitant) evaluated on $\partial\Omega$. The domain of $\mathbf{L}^+$ is determined by selecting adjoint boundary conditions, represented here in operator form as

$$\{ \mathbf{B}^+(\mathbf{u}^0, \boldsymbol{\alpha}^0; \boldsymbol{\psi}_s) - \mathbf{A}^+(\boldsymbol{\alpha}^0) \}_{\partial\Omega} = 0, \quad s \in S. \quad (83)$$

The above adjoint boundary conditions are determined by requiring that: (1) the relation (83) must be independent of $\mathbf{h}$ and $\mathbf{F}$, and (2) substitution of (83) and (79) into $\{ \mathbf{P}(\mathbf{h}, \boldsymbol{\psi}_s) \}_{\partial\Omega}$ must cause all terms containing unknown values of $\mathbf{h}$ to vanish. This selection of the adjoint boundary conditions reduces $\{ \mathbf{P}(\mathbf{h}, \boldsymbol{\psi}_s) \}_{\partial\Omega}$, to a quantity, denoted here as $\hat{\mathbf{P}}(\mathbf{F}, \boldsymbol{\psi}_s, \mathbf{u}^0, \boldsymbol{\alpha}^0)$, that contains

only known values of F , ψ_s , $\mathbf{u}^0$, and α^0 . In particular, $\hat{P}$ may vanish as a result of this selection of B^+ and A^+ . Furthermore, this selection of B^+ and A^+ , and the subsequent reduction of $\{P(h, \psi_s)\}_{\partial\Omega}$ to $\hat{P}(F, \psi_s, \mathbf{u}^0, \alpha^0)$ reduces (82) to

$$\langle \psi_s, N'_1(\mathbf{u}^0, \alpha^0) h \rangle_Q - \hat{P}(F, \psi_s, \mathbf{u}^0, \alpha^0) = \langle L^+(\mathbf{u}^0, \alpha^0) \psi_s, h \rangle_u, \quad s \in S. \quad (84)$$

Requiring now that the first terms on the right-sides of (84) and (79), respectively, represent the same functional of h yields the relation

$$L^+(\mathbf{u}^0, \alpha^0) \psi_s = M(\mathbf{u}^0, \alpha^0) p_s, \quad s \in S, x \in S, \quad (85)$$

which holds uniquely by virtue of the Riesz representation theorem. The system represented by (85) is the adjoint sensitivity system. Furthermore, using (84) and (85) in (81) reduces the latter to

$$\langle p_s, R'_1 h \rangle_R = \langle \psi_s, N'_1 h \rangle_Q - \hat{P}(F, \psi_s, \mathbf{u}^0, \alpha^0), \quad s \in S. \quad (86)$$

Replacing now $N'_1 h$ in (86) by the expression on the right-side of (78), substituting the resulting expression into the right-side of (80), and using (77) yields the following expression for the local sensitivity $DR_F(\mathbf{u}^0, \alpha^0, F)$ of the response R to the feedback F :

$$DR_F = R'_2(\mathbf{u}^0, \alpha^0) F(\mathbf{u}^0) + \sum_{s \in S} \left\{ \langle \psi_s, [Q'(\alpha^0) - N'_2(\mathbf{u}^0, \alpha^0)] F(\mathbf{u}^0) \rangle_Q - \hat{P}(F, \psi_s, \mathbf{u}^0, \alpha^0) \right\} p_s. \quad (87)$$

It is important to note that the unknown (forward) functions h do not appear in the above expression for the local sensitivity DR_F , which means that the need to solve (78) and (79) has been eliminated. Instead, it is necessary to compute as many adjoint functions ψ_s by solving (85) subject to the adjoint boundary conditions represented by (83) as there are nonzero terms retained in the summation representation in (87). In practice, this number of nonzero terms (and hence the number of required adjoint functions) is dictated by accuracy considerations, and varies from application to application. *Minimizing the number of terms in this summation falls within the objective of research activities known as “reduced-order modeling,”* but a detailed description of these activities is beyond the scope of this chapter.

Note that an expression similar to (87) holds also for systems without feedback. For such systems, the parameter variations are independent of the state variables $\mathbf{u}$ and hence do not induce feedback via $\mathbf{u}^f$. The feedback operator $F(\mathbf{u}^0)$ reduces, in such cases, simply to parameter variations, that is, $F(\mathbf{u}^0) = \alpha - \alpha^0 \equiv h_\alpha$. Consequently, the expression (87) giving the sensitivity of responses to parameters in systems without feedback reduces to

$$DR_F = R'_\alpha(\mathbf{u}^0, \alpha^0) h_\alpha + \sum_{s \in S} \left\{ \langle \psi_s, [Q'(\alpha^0) - N'_\alpha(\mathbf{u}^0, \alpha^0)] h_\alpha \rangle_Q - \hat{P}(F, \psi_s, \mathbf{u}^0, \alpha^0) \right\} p_s, \quad (88)$$

where $h_\alpha \equiv \alpha - \alpha^0$ denotes the I -component (column) vector of parameter variations around the nominal values α^0 . As before, when R is a functional of $\mathbf{u}$ and α , then the summation in (88) reduces to a single term, and only a single adjoint function would need to be calculated for obtaining DR_F .

The customary applications of DR_F as given by (87) are for:

1. Ranking the importance of feedbacks or parameter variations in affecting the response R ;
2. Uncertainty analysis (deterministic, response surface, Monte Carlo, etc.);
3. System improvements and/or design;
4. Inclusion of experimental information (e.g., via data adjustment procedures) to obtain best estimate codes;
5. Reduction of uncertainties in models;
6. Assessing the first-order local variations in R caused by feedback and/or parameter changes F by means of the functional Taylor expansion

$$R[u^f, \alpha^0 + F(u^f)] - R(u^0, \alpha^0) = DR_F(u^0, \alpha^0, F) + H.O.T(h, F), \quad (89)$$

where $H.O.T(h, F)$ denotes higher (than first-) order terms in $\|h\|$ and $\|F\|$.

For *linear systems*, the representation (68) and (69) reduce, respectively, to

$$L(\alpha)u = Q[\alpha(x)], \quad x \in \Omega, \quad (90)$$

$$[B(\alpha)u - A(\alpha)]_{\partial\Omega} = 0, \quad x \in \partial\Omega. \quad (91)$$

Consequently, the *forward sensitivity system* defined by (78) and (79) reduces to

$$L(\alpha^0)h_u + [L'_\alpha(\alpha^0)u^0]h_\alpha - \delta Q(\alpha^0; h_\alpha) = 0, \quad x \in \Omega, \quad (92)$$

$$\{B(\alpha^0)h_u + [B'_\alpha(\alpha^0)u^0]h_\alpha - \delta A(\alpha^0; h_\alpha)\}_{\partial\Omega} = 0, \quad x \in \partial\Omega, \quad (93)$$

where $L'_\alpha(\alpha^0)$ and $B'_\alpha(\alpha^0)$ denote, respectively, the partial G-derivatives at α^0 of L and B with respect to α . The adjoint sensitivity system, cf. (85) and (83) becomes

$$L^+(\alpha^0)\psi_s = M(\alpha^0)p_s, \quad s \in S, x \in \Omega, \quad (94)$$

subject to the adjoint boundary conditions

$$\{B^+(\psi_s; \alpha^0) - A^+(\alpha^0)\}_{\partial\Omega} = 0, \quad s \in S, x \in \partial\Omega. \quad (95)$$

It is important to note that the adjoint sensitivity system, consisting of (94) and (95) is independent of the nominal solution u^0 . This means that for *linear systems*, the ensuing adjoint sensitivity system can be solved independently of the solution u^0 of the original equations. This fact simplifies considerably the choice of numerical methods for solving the adjoint system.

The derivations that yielded relation (88) remain formally unchanged in the case of linear systems, giving the following expression for the sensitivity $DR(e^0; h)$ of $R(e)$ at e^0 :

$$DR(e^0; h) = R'_\alpha(e^0)h_\alpha + \sum_{s \in S} \left[\langle \psi_s, \delta Q(\alpha^0; h_\alpha) - [L'_\alpha(\alpha^0)u^0]h_\alpha \rangle_Q - \dot{P}(h_\alpha, \psi_s; \alpha^0) \right] p_s. \quad (96)$$

4.3 Sensitivity Analysis of Augmented Systems with Feedback

Consider now that the primary (original, nonaugmented) nonlinear system, represented by (68) and (69), is augmented by additional equations, containing additional independent variables, additional dependent variables, and additional parameters. A general way to represent mathematically such an augmentation process is as follows:

1. The augmented system may depend on more independent variables than the original system. To reflect this possibility, the original phase-space position vector, $\mathbf{x} = (x_1, \dots, x_{J_x})$, $\mathbf{x} \in \Omega_x \subset \mathbb{R}^{J_x}$, is augmented by the additional phase-space position vector $\mathbf{y} \equiv [y_1, \dots, y_{J_y}]$; $\mathbf{y} \in \Omega_y \subset \mathbb{R}^{J_y}$, where Ω_y is a subset of the J_y -dimensional real vector space $\mathbb{R}^{J_y}$. Thus, the phase-space position vector for the (entire) augmented system will be denoted as $\mathbf{z} \equiv (\mathbf{x}, \mathbf{y})$; $J \equiv J_x + J_y$; $\mathbf{z} \in \Omega \equiv \Omega_x \cup \Omega_y \subset \mathbb{R}^J$.
2. The augmented system may comprise more dependent variables than the original system. To reflect this possibility, the original vector of dependent (i.e., state) variables, $\mathbf{u}(\mathbf{x}) = [u_1(\mathbf{x}), \dots, u_{K_u}(\mathbf{x})]$, $\mathbf{u}(\mathbf{x}) \in E_u$, is augmented by the vector of additional dependent variables $\mathbf{v}(\mathbf{z}) = [v_1(\mathbf{z}), \dots, v_{K_v}(\mathbf{z})]$, $\mathbf{v}(\mathbf{z}) \in E_v$ where E_v is a normed linear space over the scalar field F of real numbers, and where K_v denotes the total number of additional state (i.e., dependent) variables appearing in the augmented system.
3. The augmented system may depend on more parameters than the original system; furthermore, components of the original vector of system parameters, $\boldsymbol{\alpha}(\mathbf{x}) = [\alpha_1(\mathbf{x}), \dots, \alpha_I(\mathbf{x})]$, $\boldsymbol{\alpha} \in E_\alpha$, can become functions of additional parameters, $\mathbf{b}(\mathbf{z}) = [b_1(\mathbf{z}), \dots, b_{I_b}(\mathbf{z})]$, $\mathbf{b} \in E_b$, where E_b is a normed linear space. In addition, feedback may be introduced in the augmented system, if some (or all) of the parameters $\boldsymbol{\alpha}$ become dependent on some (or all) of the components of $\mathbf{u}(\mathbf{x}) \in E_u$ and/or the components of $\mathbf{v}(\mathbf{z}) \in E_v$. Finally, a subset $\boldsymbol{\beta}(\mathbf{x}) = [\beta_1(\mathbf{x}), \dots, \beta_{I_\beta}(\mathbf{x})]$, $\boldsymbol{\beta} \in E_\beta$, where E_β is also a normed linear space, of the original parameters may remain unaffected by the transition from the original to the enlarged, augmented system. In a very general manner, therefore, the transition from the original system to the enlarged, augmented system can be described mathematically by the mapping $\alpha \rightarrow \mathbf{a}[\boldsymbol{\beta}(\mathbf{x}), \mathbf{b}(\mathbf{z}); \mathbf{u}(\mathbf{x}), \mathbf{v}(\mathbf{z})]$, $\mathbf{a} \in E_a$. Note that the normed linear space E_a for the augmented system will generally differ from the normed linear space E_α to which the parameters of the original (unaugmented) system belonged.
4. In view of the extensions described above in items 1–3, the operators appearing in (68) will undergo the following transformations:

$$\begin{aligned}
 N(\mathbf{u}, \boldsymbol{\alpha}) &\rightarrow N[\mathbf{u}, \mathbf{a}(\boldsymbol{\beta}(\mathbf{x}), \mathbf{b}(\mathbf{z}); \mathbf{u}(\mathbf{x}), \mathbf{v}(\mathbf{z}))] \\
 &\equiv [N_1(\mathbf{u}, \mathbf{a}(\boldsymbol{\beta}, \mathbf{b}; \mathbf{u}, \mathbf{v})), \dots, N_{K_u}(\mathbf{u}, \mathbf{a}(\boldsymbol{\beta}, \mathbf{b}; \mathbf{u}, \mathbf{v}))] \\
 Q[\boldsymbol{\alpha}(\mathbf{x})] &\rightarrow Q[\mathbf{a}(\boldsymbol{\beta}(\mathbf{x}), \mathbf{b}(\mathbf{z}); \mathbf{u}(\mathbf{x}), \mathbf{v}(\mathbf{z}))] \\
 &\equiv [Q_1[\mathbf{a}(\boldsymbol{\beta}, \mathbf{b}; \mathbf{u}, \mathbf{v})], \dots, Q_{K_u}[\mathbf{a}(\boldsymbol{\beta}, \mathbf{b}; \mathbf{u}, \mathbf{v})]].
 \end{aligned}$$

Note also that, for the augmented system, $\mathbf{Q} \in E_q$, where E_q is a normed linear space that differs from the original normed linear space E_Q . Similarly, the boundary operators appearing in (69) will undergo the transformations $A(\boldsymbol{\alpha}) \rightarrow A[\mathbf{a}(\boldsymbol{\beta}, \mathbf{b}; \mathbf{u}, \mathbf{v})]$ and $B(\mathbf{u}, \boldsymbol{\alpha}) \rightarrow B[\mathbf{u}(\mathbf{x}); \mathbf{a}(\boldsymbol{\beta}, \mathbf{b}; \mathbf{u}, \mathbf{v})]$,

respectively. Therefore, (68) and (69) will be mapped into the following forms within the augmented system:

$$N[u, a(\beta, b; u, v)] = Q[a(\beta, b; u, v)], \quad z \in \Omega, \quad (97)$$

$$B[u, a(\beta, b; u, v)] = A[a(\beta, b; u, v)], \quad z \in \partial\Omega. \quad (98)$$

In addition to the relations (97) and (98), the augmented system will also contain further equations and corresponding boundary and/or initial conditions, as needed to balance the total number of state (i.e., dependent) variables (u, v) with the total number of equations, in order to have a well-posed augmented system. These additional equations can be written in operator form as

$$M[u(x), v(z), b(z)] = S(b), \quad z \in \Omega, \quad (99)$$

with corresponding boundary and/or initial conditions written in operator form as

$$C[u(x), v(z), b(z)] = D(b), \quad z \in \partial\Omega. \quad (100)$$

Each of the vector-valued operators appearing in (99) comprise K_v -components of the form

$$\begin{aligned} M[u(x), v(z), b(z)] &\equiv [M_1(u, v, b), \dots, M_{K_v}(u, v, b)], \\ S[u(x), v(z), b(z)] &\equiv [S_1(u, v, b), \dots, S_{K_v}(u, v, b)], \quad S \in E_S. \end{aligned}$$

In view of the definitions given above, the augmented vector of operators (N, M) represents the mapping $(N, M) : D_{\text{aug}} \subset E_{\text{aug}} \rightarrow E_q \times E_S$, where $D_{\text{aug}} = D_u \times D_v \times D_a$, $D_u \subset E_u$, $D_v \subset E_v$, $D_a \subset E_a$, and $E_{\text{aug}} = E_u \times E_v \times E_a$. The subscript “aug” denotes “augmented space.” Note that a generic element $f \in E_{\text{aug}}$ is of the form $f \equiv [u, v, a(\beta, b; u, v)]$. The vector-valued function $[u(x), v(z)]$ is considered to be the unique nontrivial solution of the physical problem described by (97) through (99).

The system response (i.e., performance parameter) associated with the augmented system modeled by (97–100) will be denoted in the sequel as $\Theta(f)$, and is considered to be an operator that acts nonlinearly on the augmented system’s state vector $[u(x), v(z)]$ and parameters $a(\beta, b; u, v)$; $\Theta(f)$ can be represented in operator form as the mapping $\Theta(f) : D_{\text{Raug}} \subset E_{\text{aug}} \rightarrow E_{\text{Raug}}$, where E_{Raug} is another normed vector space.

In practice, the exact values of the parameters α , β , and b are not known exactly; only their nominal (mean) values, α^0 , β^0 , and b^0 , and their associated uncertainties are usually available. The nominal parameter values a^0 are used in (97–100) to obtain the nominal solution $[u^0(x), v^0(z)]$, by solving the “base-case” augmented system

$$N[u^0, a^0(\beta^0, b^0; u^0, v^0)] = Q[a^0(\beta^0, b^0; u^0, v^0)], \quad z \in \Omega, \quad (101)$$

$$B[u^0, a^0(\beta^0, b^0; u^0, v^0)] = A[a^0(\beta^0, b^0; u^0, v^0)], \quad z \in \partial\Omega, \quad (102)$$

$$M[u^0(x), v^0(z), b^0(z)] = S(b^0), \quad z \in \Omega, \quad (103)$$

$$C[u^0(x), v^0(z), b^0(z)] = D(b^0), \quad z \in \partial\Omega. \quad (104)$$

Using the base-case solution of the augmented system obtained by solving (101–104) yields the base-case value, $\Theta(f^0)$, $f^0 \equiv [u^0, v^0, a^0(\beta^0, b^0; u^0, v^0)]$, of the response for the augmented system.

The sensitivity of the response, $\Theta(f)$, at $f^0 \equiv [u^0, v^0, a^0(\beta^0, b^0; u^0, v^0)]$ to variations $h \equiv [h_u, h_v, h_\beta, h_b]$ in the augmented system's parameters is the Gâteaux-(G)-differential, $\delta\Theta(f^0; h)$, defined as

$$\delta\Theta(f^0; h) \equiv \left\{ \frac{d}{dt} [\Theta(f^0 + th)] \right\}_{t=0} = \lim_{t \rightarrow 0} \frac{\Theta(f^0 + th) - \Theta(f^0)}{t}, \quad (105)$$

for $t \in \mathbb{F}$, and all (i.e., arbitrary) vectors $f \in E_{\text{aug}}$.

4.3.1 The Forward Sensitivity Analysis Procedure (FSAP)

Just as for the original system, the augmented system's state vector $[u(x), v(z)]$ and parameters (β, b) are related to each other through the relations (97–100). Hence, it follows that the vector of variations (h_u, h_v) around the nominal values $[u^0(x), v^0(z)]$ of the state functions $[u(x), v(z)]$ is also related to the vector of parameter variations (h_β, h_b) around the nominal values (β^0, b^0) . Therefore, the sensitivity $\delta\Theta(f^0; h)$ of $\Theta(f)$ at f^0 can only be evaluated after determining the variations (h_u, h_v) in terms of the vector of parameter variations (h_β, h_b) . The first-order relationship between (h_u, h_v) and (h_β, h_b) is obtained by taking the G-differentials of (101–104), to obtain the relations

$$\begin{pmatrix} N'_u(f^0) + [N'_a(f^0) - Q'_a(f^0)] a'_u(f^0) & [N'_a(f^0) - Q'_a(f^0)] a'_v(f^0) \\ M'_u(f^0) & M'_v(f^0) \end{pmatrix} \begin{pmatrix} h_u \\ h_v \end{pmatrix} \\ = \begin{pmatrix} [Q'_a(f^0) - N'_a(f^0)] a'_\beta(f^0) & [Q'_a(f^0) - N'_a(f^0)] a'_b(f^0) \\ 0 & S'_b(b^0) - M'_b(f^0) \end{pmatrix} \begin{pmatrix} h_\beta \\ h_b \end{pmatrix} \quad (106)$$

together with the G-differentiated boundary/initial conditions

$$\begin{aligned} B'_u(f^0) h_u + [B'_a(f^0) - A'_a(f^0)] [a'_u(f^0) h_u + a'_v(f^0) h_v] \\ = [A'_a(f^0) - B'_a(f^0)] \times [a'_\beta(f^0) h_\beta + a'_b(f^0) h_b], \quad z \in \partial\Omega, \end{aligned} \quad (107)$$

$$C'_u(f^0) h_u + C'_v(f^0) h_v = \delta D(b^0; h_b) - C'_b(f^0) h_b, \quad z \in \partial\Omega. \quad (108)$$

Note that the left-side of (4.39) represents a block-matrix-valued linear operator, $L_a(f^0)$, defined as

$$\begin{aligned} L_a(f^0) &\equiv \begin{pmatrix} L_{11}(f^0) & L_{12}(f^0) \\ L_{21}(f^0) & L_{22}(f^0) \end{pmatrix} \\ &\equiv \begin{pmatrix} N'_u(f^0) + [N'_a(f^0) - Q'_a(f^0)] a'_u(f^0) & [N'_a(f^0) - Q'_a(f^0)] a'_v(f^0) \\ M'_u(f^0) & M'_v(f^0) \end{pmatrix}. \end{aligned} \quad (109)$$

In the above expressions, the subscript “a” denotes “augmented.” For a given vector of parameter variations (h_β, h_b) , the system of equations (106–108) can be solved to obtain, to first-order, the vector of variations (h_u, h_v) . In turn, the variations (h_u, h_v) and (h_β, h_b) are used in (105) to calculate the sensitivity $\delta\Theta(f^0; h)$ of $\Theta(f)$ at f^0 , for given parameter variations (h_β, h_b) . Equations (106–108) represent the “forward sensitivity equations (FSE),” [also called the “tangent

linear model (TLM)"]. The forward sensitivity analysis procedure (FSAP) would proceed with the direct calculation of the response sensitivity $\delta\Theta(\mathbf{f}^0; \mathbf{h})$ by using the $(\mathbf{h}_\beta, \mathbf{h}_b)$ -dependent solution of the forward sensitivity equations. From the standpoint of computational costs and effort, the FSAP is advantageous to employ only if, in the problem under consideration, the number of different responses of interest exceeds the number of system parameters and/or parameter variations to be considered.

4.3.2 The Adjoint Sensitivity Analysis Procedure (ASAP)

The practical motivation underlying the development of an alternative method for sensitivity analysis is to avoid the need for repeatedly solving the FSE represented by (106–108). This goal was achieved for the original (unaugmented) system by constructing an adjoint system that was (1) uniquely defined, (2) independent of the vectors $\mathbf{h}_u$ and $\mathbf{h}_\alpha$, and (3) such that its solution can be used to eliminate all unknown values of $\mathbf{h}_u$ from the expression of $\delta\Theta(\mathbf{f}^0; \mathbf{h})$. A similar path will also be followed for the augmented system. For this purpose, the spaces E_u , E_v , E_S , and E_q will henceforth be considered to be real Hilbert spaces denoted by H_u , H_v , H_q , and H_S , respectively. The inner products on $H_u \times H_v$ and $H_q \times H_S$ will be denoted by $\langle \bullet, \bullet \rangle_{u \times v}$ and $\langle \bullet, \bullet \rangle_{q \times S}$, respectively.

To define the formal adjoint $L_a^+(\mathbf{f}^0)$ of $L_a(\mathbf{f}^0)$, we recall from the geometry of Hilbert spaces $H_u \times H_v$ and $H_q \times H_S$ that the following relationship holds for a (column) vector $(\psi_u, \psi_v)^T \in H_q \times H_S$, where the superscript “ T ” denotes “transposition”:

$$\begin{aligned} & \left\langle \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix}^T, \begin{pmatrix} L_{11}(\mathbf{f}^0) & L_{12}(\mathbf{f}^0) \\ L_{21}(\mathbf{f}^0) & L_{22}(\mathbf{f}^0) \end{pmatrix} \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix} \right\rangle_{q \times S} \\ &= \left\langle \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix}^T, L_a^+(\mathbf{f}^0) \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix} \right\rangle_{u \times v} + \{P(\mathbf{f}^0; \psi_u, \psi_v; \mathbf{h}_u, \mathbf{h}_v)\}_{\partial\Omega}. \end{aligned} \quad (110)$$

The quantity $\{P(\mathbf{f}^0; \psi_u, \psi_v; \mathbf{h}_u, \mathbf{h}_v)\}_{\partial\Omega}$ in the above equation denotes the associated bilinear form (the “bilinear concomitant”) evaluated on $\partial\Omega$.

Replacing (109) on the left-side of (110) and carrying out the operations indicated by the respective inner products shows that the explicit form for the formal adjoint operator $L_a^+(\mathbf{f}^0)$ is the following 2×2 block-matrix:

$$\begin{aligned} L_a^+(\mathbf{f}^0) &\equiv \begin{pmatrix} L_{11}^+(\mathbf{f}^0) & L_{12}^+(\mathbf{f}^0) \\ L_{21}^+(\mathbf{f}^0) & L_{22}^+(\mathbf{f}^0) \end{pmatrix} \\ &\equiv \begin{pmatrix} [N'_u(\mathbf{f}^0)]^+ + \{[N'_a(\mathbf{f}^0) - Q'_a(\mathbf{f}^0)]\mathbf{a}'_u(\mathbf{f}^0)\}^+ & [M'_u(\mathbf{f}^0)]^+ \\ \{[N'_a(\mathbf{f}^0) - Q'_a(\mathbf{f}^0)]\mathbf{a}'_v(\mathbf{f}^0)\}^+ & [M'_v(\mathbf{f}^0)]^+ \end{pmatrix}, \end{aligned} \quad (111)$$

where the quantities $[N'_u(\mathbf{f}^0)]^+$, $\{[N'_a(\mathbf{f}^0) - Q'_a(\mathbf{f}^0)]\mathbf{a}'_u(\mathbf{f}^0)\}^+$, $[M'_u(\mathbf{f}^0)]^+$, $\{[N'_a(\mathbf{f}^0) - Q'_a(\mathbf{f}^0)]\mathbf{a}'_v(\mathbf{f}^0)\}^+$, and $[M'_v(\mathbf{f}^0)]^+$, denote the formal adjoint operators corresponding to $N'_u(\mathbf{f}^0)$, $[N'_a(\mathbf{f}^0) - Q'_a(\mathbf{f}^0)]\mathbf{a}'_u(\mathbf{f}^0)$, $M'_u(\mathbf{f}^0)$, $[N'_a(\mathbf{f}^0) - Q'_a(\mathbf{f}^0)]\mathbf{a}'_v(\mathbf{f}^0)$, and $M'_v(\mathbf{f}^0)$, respectively.

The boundary conditions for the adjoint operator $L_a^+(f^0)$, which define its domain, must be determined next. They are represented here in operator form as

$$\{\Gamma_1^+(f^0; \psi_u, \psi_v) - \Gamma_2^+(f^0)\}_{\partial\Omega} = 0, \quad \mathbf{z} \in \partial\Omega, \quad (112)$$

and are determined by requiring that (1) they must be independent of $(\mathbf{h}_u, \mathbf{h}_v)$ and $(\mathbf{h}_\beta, \mathbf{h}_b)$, and G-derivatives with respect to β and $\mathbf{b}$; (2) they must cause all terms containing unknown values of $(\mathbf{h}_u, \mathbf{h}_v)$ to vanish when substituted together with (107) and (108) into the expression of $\{P(f^0; \psi_u, \psi_v; \mathbf{h}_u, \mathbf{h}_v)\}_{\partial\Omega}$.

Thus, when the conditions (112) for $L_a^+(f^0)$ are substituted together with (107) and (108) into the expression of $\{P(f^0; \psi_u, \psi_v; \mathbf{h}_u, \mathbf{h}_v)\}_{\partial\Omega}$, this bilinear concomitant will be reduced to a quantity that contains boundary terms involving solely known values of $(\mathbf{h}_\beta, \mathbf{h}_b)$, (ψ_u, ψ_v) , and, possibly, f^0 ; this quantity will be denoted in the sequel by $\hat{P}(f^0; \psi_u, \psi_v; \mathbf{h}_\beta, \mathbf{h}_b)$. In general, $\hat{P}(f^0; \psi_u, \psi_v; \mathbf{h}_\beta, \mathbf{h}_b)$ does not automatically vanish as a result of these manipulations, although it may do so in particular instances. In practice, $\hat{P}(f^0; \psi_u, \psi_v; \mathbf{h}_\beta, \mathbf{h}_b)$ will ultimately appear as a readily computable quantity in the expression of the response sensitivity $\delta\Theta(f^0; \mathbf{h})$.

Replacing now (107) and (108) together with the adjoint boundary conditions, given in (112) for $L_a^+(f^0)$, into (110) reduces the latter equation to

$$\begin{aligned} & \left\langle \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix}^T, \begin{pmatrix} L_{11}(f^0) & L_{12}(f^0) \\ L_{21}(f^0) & L_{22}(f^0) \end{pmatrix} \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix} \right\rangle_{q \times S} \\ &= \left\langle \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix}^T, L_a^+(f^0) \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix} \right\rangle_{u \times v} + \hat{P}(f^0; \psi_u, \psi_v; \mathbf{h}_\beta, \mathbf{h}_b). \end{aligned} \quad (113)$$

Replacing the quantity $\begin{pmatrix} L_{11}(f^0) & L_{12}(f^0) \\ L_{21}(f^0) & L_{22}(f^0) \end{pmatrix} \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix}$ by the quantity $\begin{pmatrix} [Q'_a(f^0) - N'_a(f^0)] \mathbf{a}'_\beta(f^0) & [Q'_a(f^0) - N'_a(f^0)] \mathbf{a}'_b(f^0) \\ 0 & S'_b(b^0) - M'_b(f^0) \end{pmatrix} \begin{pmatrix} \mathbf{h}_\beta \\ \mathbf{h}_b \end{pmatrix}$ in the relation (113) transforms the latter into the form

$$\begin{aligned} & \left\langle \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix}^T, L_a^+(f^0) \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix} \right\rangle_{u \times v} = -\hat{P}(f^0; \psi_u, \psi_v; \mathbf{h}_\beta, \mathbf{h}_b) \\ & + \left\langle \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix}^T, \begin{pmatrix} [Q'_a(f^0) - N'_a(f^0)] \mathbf{a}'_\beta(f^0) & [Q'_a(f^0) - N'_a(f^0)] \mathbf{a}'_b(f^0) \\ 0 & S'_b(b^0) - M'_b(f^0) \end{pmatrix} \begin{pmatrix} \mathbf{h}_\beta \\ \mathbf{h}_b \end{pmatrix} \right\rangle_{q \times S} \end{aligned} \quad (114)$$

To complete the ASAP, the left-side of the above equation needs to be related to the sensitivity $\delta\Theta(f^0; \mathbf{h})$ defined by (105). This can be done only when $\Theta(f)$ satisfies a weak Lipschitz condition at f^0 , and also satisfies the relation

$$\Theta(f^0 + t\mathbf{h}_1 + t\mathbf{h}_2) - \Theta(f^0 + t\mathbf{h}_1) - \Theta(f^0 + t\mathbf{h}_2) + \Theta(f^0) = o(t) \quad (115)$$

for two arbitrary vectors of increments $\mathbf{h}_1$ and $\mathbf{h}_2$ that have the same form (and the same number of components) as $\mathbf{h}$. In such cases, the response sensitivity $\delta\Theta(f^0; \mathbf{h})$ is linear in

$\mathbf{h} \equiv [\mathbf{h}_u, \mathbf{h}_v, \mathbf{h}_\beta, \mathbf{h}_b]$, and therefore becomes the total G-derivative $D\Theta(\mathbf{f}^0; \mathbf{h})$ of $\Theta(\mathbf{f})$ at $\mathbf{f}^0$, of the form

$$\begin{aligned} D\Theta(\mathbf{f}^0; \mathbf{h}) &= \Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v \\ &\quad + \Theta'_a(\mathbf{f}^0) [\mathbf{a}'_\beta(\mathbf{f}^0) \mathbf{h}_\beta + \mathbf{a}'_b(\mathbf{f}^0) \mathbf{h}_b]. \end{aligned} \quad (116)$$

In the above expression, the quantities $\Theta'_u(\mathbf{f}^0)$, $\Theta'_v(\mathbf{f}^0)$, and $\Theta'_a(\mathbf{f}^0)$, denote the respective partial G-derivatives of $\Theta(\mathbf{f})$ at $\mathbf{f}^0$, while $\mathbf{a}'_v(\mathbf{f}^0)$, $\mathbf{a}'_\beta(\mathbf{f}^0)$, and $\mathbf{a}'_b(\mathbf{f}^0)$ denote the respective partial G-derivatives of $\mathbf{a}(\mathbf{f})$ at $\mathbf{f}^0$.

As indicated by (116), the $(\mathbf{h}_u, \mathbf{h}_v)$ -dependence in $D\Theta(\mathbf{f}^0; \mathbf{h})$ is separated from the $(\mathbf{h}_\beta, \mathbf{h}_b)$ -dependence. Furthermore, the 2-component column block-vector $[\Theta'_u(\mathbf{f}^0), \Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)]^T$ operates linearly on the vector $(\mathbf{h}_u, \mathbf{h}_v)^T$, which implies that

$$[\Theta'_u(\mathbf{f}^0), \Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)]^T \in L(H_u \times H_v, H_{\text{Raug}}(\Omega_{\text{Raug}}))$$

The *direct effect term* $\Theta'_a(\mathbf{f}^0) [\mathbf{a}'_\beta(\mathbf{f}^0) \mathbf{h}_\beta + \mathbf{a}'_b(\mathbf{f}^0) \mathbf{h}_b]$ can be calculated directly at this stage. On the other hand, the quantity $\Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v$ cannot be evaluated directly at this stage, since it depends on the unknown vector-valued function $(\mathbf{h}_u, \mathbf{h}_v)^T$, and is therefore called the *indirect effect term*.

To proceed with the evaluation of the indirect effect term $\{\Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v\} \in H_{\text{Raug}}(\Omega_{\text{Raug}})$, we consider that the orthonormal set $\{\theta_s\}_{s \in S}$, where s runs through an index set S , is an orthonormal basis of $H_{\text{Raug}}(\Omega_{\text{Raug}})$. Therefore, the indirect effect term $\Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v$ can be represented as the Fourier series

$$\begin{aligned} &\Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v \\ &= \sum_{s \in S} \langle \Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v, \theta_s \rangle_{\text{Raug}} \theta_s. \end{aligned} \quad (117)$$

The notation $\sum_{s \in S}$ is used to signify that in the above sum only an at most countable number of elements are different from zero, and the series extended upon the nonzero elements converges unconditionally. According to customary terminology, the functionals $\langle \Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v, \theta_s \rangle_{\text{Raug}}$ are called the Fourier coefficients with respect to the basis $\{\theta_s\}$, and are linear functionals in $(\mathbf{h}_u, \mathbf{h}_v)^T$.

The next step is to express each of the functionals $\langle \Theta'_u(\mathbf{f}^0) \mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \mathbf{h}_v, \theta_s \rangle_{\text{Raug}}$ as an inner product of $(\mathbf{h}_u, \mathbf{h}_v)^T$ with a uniquely defined vector in $H_u \times H_v$, which remains to be determined. Recalling that $[\Theta'_u(\mathbf{f}^0), \Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)]^T \in L(H_u \times H_v, H_{\text{Raug}}(\Omega_{\text{Raug}}))$, it follows that we can define the linear operator $\Pi(\mathbf{f}^0) \in L(H_{\text{Raug}}(\Omega_{\text{Raug}}), H_u \times H_v)$ to be the adjoint of $[\Theta'_u(\mathbf{f}^0), \Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)]^T \in L(H_u \times H_v, H_{\text{Raug}}(\Omega_{\text{Raug}}))$, by means of the relationship

$$\left\langle [\Theta'_u(\mathbf{f}^0) \Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0) \mathbf{a}'_v(\mathbf{f}^0)] \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix}, \theta_s \right\rangle_R = \left\langle \Pi(\mathbf{f}^0) \theta_s, \begin{pmatrix} \mathbf{h}_u \\ \mathbf{h}_v \end{pmatrix} \right\rangle_{u \times v}, \quad s \in S. \quad (118)$$

The operator $\Pi(\mathbf{e}^0)$ is actually a two-component operator (with components of dimensions equal to the vectors $\mathbf{h}_u$ and $\mathbf{h}_v$, respectively), and is unique if

$\Theta'_u(\mathbf{f}^0)\mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0)\mathbf{a}'_v(\mathbf{f}^0)]\mathbf{h}_v$ is densely defined. The right-side of (118) can now be required to represent the same functional as the left-side of (114); this requirement yields the adjoint sensitivity system

$$\mathbf{L}_a^+(\mathbf{f}^0) \begin{pmatrix} \psi_u^s \\ \psi_v^s \end{pmatrix} \equiv \begin{pmatrix} \mathbf{L}_{11}^+(\mathbf{f}^0) & \mathbf{L}_{12}^+(\mathbf{f}^0) \\ \mathbf{L}_{21}^+(\mathbf{f}^0) & \mathbf{L}_{22}^+(\mathbf{f}^0) \end{pmatrix} \begin{pmatrix} \psi_u^s \\ \psi_v^s \end{pmatrix} = \mathbf{\Pi}(\mathbf{f}^0) \boldsymbol{\theta}_s, \quad s \in S, \quad (119)$$

which holds uniquely in view of the Riesz representation theorem. Note that the superscript s has been used to indicate the particular adjoint functions that are solutions of (119). This last step completes the construction of the *adjoint sensitivity system*, which consists of (119) and boundary conditions given in (112) for the adjoint function $(\psi_u^s, \psi_v^s)^T$. Furthermore, the relation (114) together with the relations (116–118) can now be used to obtain the following expression for the sensitivity $D\Theta(\mathbf{f}^0; \mathbf{h})$ of $\Theta(\mathbf{f})$ at $\mathbf{f}^0$:

$$\begin{aligned} D\Theta(\mathbf{f}^0; \mathbf{h}) &= \Theta'_a(\mathbf{f}^0) [\mathbf{a}'_\beta(\mathbf{f}^0) \mathbf{h}_\beta + \mathbf{a}'_b(\mathbf{f}^0) \mathbf{h}_b] + \sum_{s \in S} \boldsymbol{\theta}_s [-\hat{\mathbf{P}}(\mathbf{f}^0; \psi_u^s, \psi_v^s; \mathbf{h}_\beta, \mathbf{h}_b) \\ &+ \left(\begin{pmatrix} \psi_u^s \\ \psi_v^s \end{pmatrix}^T, \begin{pmatrix} [\mathbf{Q}'_a(\mathbf{f}^0) - \mathbf{N}'_a(\mathbf{f}^0)] \mathbf{a}'_\beta(\mathbf{f}^0) & [\mathbf{Q}'_a(\mathbf{f}^0) - \mathbf{N}'_a(\mathbf{f}^0)] \mathbf{a}'_b(\mathbf{f}^0) \\ 0 & \mathbf{S}'_b(\mathbf{b}^0) - \mathbf{M}'_b(\mathbf{f}^0) \end{pmatrix} \begin{pmatrix} \mathbf{h}_\beta \\ \mathbf{h}_b \end{pmatrix} \right)_{q \times S} \right]. \end{aligned} \quad (120)$$

As (120) indicates, the desired elimination of all unknown values of $(\mathbf{h}_u, \mathbf{h}_v)^T$ from the expression of the sensitivity $D\Theta(\mathbf{f}^0; \mathbf{h})$ of $\Theta(\mathbf{f})$ at $\mathbf{f}^0$ has thus been accomplished. To evaluate the sensitivity $D\Theta(\mathbf{f}^0; \mathbf{h})$ by means of (120), one needs to compute as many adjoint functions $(\psi_u^s, \psi_v^s)^T$, $(s = 1, 2, \dots)$, using (119) and (112) as there are nonzero terms in the representation of $\Theta'_u(\mathbf{f}^0)\mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0)\mathbf{a}'_v(\mathbf{f}^0)]\mathbf{h}_v$ given in (117). Although the linear combination of basis elements $\mathbf{p}_s$ given in (117) may, in principle, contain infinitely many terms, only a finite number of the corresponding adjoint functions $(\psi_u^s, \psi_v^s)^T$ can be calculated in practice. Therefore, special attention is required to select the Hilbert space $H_{\text{Raug}}(\Omega_{\text{Raug}})$, the orthonormal basis $\{\boldsymbol{\theta}_s\}_{s \in S}$ for this space, and a notion of convergence for the representation given in (117) to best suit the problem at hand. This selection is guided by the need to represent the indirect effect term $\Theta'_u(\mathbf{f}^0)\mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0)\mathbf{a}'_v(\mathbf{f}^0)]\mathbf{h}_v$ as accurately as possible with the smallest number of basis elements; a related consideration is the viability of deriving bounds and/or asymptotic expressions for the remainder after truncating (117) to the first few terms. *Minimizing the number of terms in this summation falls within the objective of research activities known as “reduced-order modeling,”* but a detailed description of these activities is beyond the scope of this chapter.

In the important practical case when the *system response is a nonlinear functional* of the form $\Theta(\mathbf{f}) : D_{\text{Raug}} \subset E_{\text{aug}} \rightarrow F$, the space E_{Raug} is the underlying scalar field F of real numbers, and the sensitivity $\delta\Theta(\mathbf{f}^0; \mathbf{h})$ also becomes a functional that takes values in F . Furthermore, it will be assumed that the response $\Theta(\mathbf{e})$ satisfies a weak Lipschitz condition at $\mathbf{f}^0$ and also satisfies the relation shown in (115), so that the linear (in $\mathbf{h}$) G-differential $D\Theta(\mathbf{f}^0; \mathbf{h})$ exists. In this case, the summation $\sum_{s \in S}$ shown in (117) for the indirect effect term $\Theta'_u(\mathbf{f}^0)\mathbf{h}_u + [\Theta'_v(\mathbf{f}^0) + \Theta'_a(\mathbf{f}^0)\mathbf{a}'_v(\mathbf{f}^0)]\mathbf{h}_v$ reduces to a single term ($s = 1$); the subscript s can therefore be omitted in the sequel. Furthermore, the Riesz representation theorem ensures that there exists a unique 2-component vector $[\nabla_u \Theta(\mathbf{f}^0), \nabla_v \Theta(\mathbf{f}^0)]^T \in H_u \times H_v$, where the

respective components are defined via the relationship

$$\begin{aligned} \Theta'_u(f^0) h_u + [\Theta'_v(f^0) + \Theta'_a(f^0) a'_v(f^0)] h_v \\ = \left[\left[\nabla_u R(f^0) \nabla_u R(f^0) \right], \begin{pmatrix} h_u \\ h_v \end{pmatrix} \right]_{u \times v}, \quad h_u \in H_u, h_v \in H_v \\ \nabla_u \Theta(f^0) \equiv [\Theta'_u(f^0)]^T \in H_u, \\ \nabla_v \Theta(f^0) \equiv [[\Theta'_v(f^0) + \Theta'_a(f^0) a'_v(f^0)]]^T \in H_v. \end{aligned} \quad (121)$$

Comparison of (122) and (118) reveals that (119) becomes

$$L_a^+(f^0) \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix} \equiv \begin{pmatrix} L_{11}^+(f^0) & L_{12}^+(f^0) \\ L_{21}^+(f^0) & L_{22}^+(f^0) \end{pmatrix} \begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix} = \begin{pmatrix} \nabla_u R(f^0) \\ \nabla_v R(f^0) \end{pmatrix}. \quad (122)$$

Furthermore, the expression for response sensitivity $D\Theta(f^0; h)$, cf. (120) reduces to

$$\begin{aligned} D\Theta(f^0; h) = \Theta'_a(f^0) [a'_\beta(f^0) h_\beta + a'_b(f^0) h_b] - \dot{P}(f^0; \psi_u, \psi_v; h_\beta, h_b) \\ + \left(\begin{pmatrix} \psi_u \\ \psi_v \end{pmatrix}^T, \begin{pmatrix} [Q'_a(f^0) - N'_a(f^0)] a'_\beta(f^0) & [Q'_a(f^0) - N'_a(f^0)] a'_b(f^0) \\ 0 & S'_b(b^0) - M'_b(f^0) \end{pmatrix} \begin{pmatrix} h_\beta \\ h_b \end{pmatrix} \right)_{q \times S}. \end{aligned} \quad (123)$$

Thus, once the single calculation to determine the adjoint function $(\psi_u, \psi_v)^T$ from (122) and (112) has been carried out, the adjoint function $(\psi_u, \psi_v)^T$ can be used in (123) to obtain efficiently the sensitivity $D\Theta(f^0; h)$ of $\Theta(f)$.

In practice, when the ASAP is applied successively to the various component modules of a complex code system, the practitioner first develops an adjoint sensitivity model of the form described by (85) and then augments the adjoint operator $L^+(e^0)$ to construct the augmented adjoint operator $L_a^+(f^0)$ defined in (111). From a programmer's point of view, the adjoint operator $L_{11}^+(f^0) \equiv [N'_u(f^0)]^+ + \{[N'_a(f^0) - Q'_a(f^0)] a'_u(f^0)\}^+$ can be formally constructed by starting from the adjoint operator $L^+(e^0) \equiv [N'_u(u^0, \alpha^0)]^+$ of the original (nonaugmented) system, and then adding the operator $\{[N'_a(f^0) - Q'_a(f^0)] a'_u(f^0)\}^+$. This is because the numerical representation of the operator $[N'_u(f^0)]^+$ is the same as that of $[N'_u(u^0, \alpha^0)]^+$. The fact that these two operators are then evaluated at distinct nominal parameter values clearly plays an important role in the solution evaluation, but not in the initial construction and programming of $L_{11}^+(f^0)$. Of course, the adjoint operators $L_{12}^+(f^0)$, $L_{21}^+(f^0)$, and $L_{22}^+(f^0)$ are specific to the augmented system, and must therefore be constructed/programmed *ab initio*.

Often, the adjoint sensitivity system for the augmented system can be solved by using the same numerical methods as used for solving the non-augmented adjoint system, particularly when the numerical representation of the matrix operator $L_a^+(f^0)$ can be inverted by partitioning. Of course, if the off-diagonal operators $L_{12}^+(f^0)$ and/or $L_{21}^+(f^0)$ vanish, then the inversion of $L_a^+(f^0)$ becomes significantly simpler.

The inverse route, namely, going from the augmented system to the non-augmented one is accomplished by simply setting the operators $L_{12}^+(f^0)$, $L_{21}^+(f^0)$, and $L_{22}^+(f^0)$ to zero. In this case, (120) also reduces to (87), as would be expected.

4.4 Illustrative Application of ASAP: Adjoint Sensitivity Analysis of Markov Dynamic Reliability Models

Markov chains are extensively used to analyze and predict system reliability and availability in many branches of industry (e.g., cell phones, computers, communication and networks, health equipment, aviation and aerospace, automotive engineering, chemical processing, military application, nuclear engineering), economic/econometric models, population forecasting, biology, and financial planning (see, e.g., Henley and Kumamoto 1992; Norris 1997). A Markov chain typically models the respective physical system as a set of states in which the system can find itself during its life period, together with the transitions that can occur between these states, accounting for statistical dependences among failures and/or repairs. A state is a unique configuration of failed and operational components or subsystems. The states and transitions for a Markov chain with $I = \{1, 2, \dots, n\}$ states are modeled by a system of ordinary differential (Kolmogorov's) equations, including the corresponding initial probability distribution, and can be written in matrix form as follows:

$$\begin{cases} \frac{d\Pi(t)}{dt} = [Q(t)] \Pi(t), & t \geq t_0 \\ \Pi(t_0) = \Pi_0, \end{cases} \quad (124)$$

where the column vector $\Pi(t)$ represents the state probability vector

$$\Pi(t) = [\pi_1(t), \pi_2(t), \dots, \pi_n(t)]^T, \quad (125)$$

and the column vector Π_0 represents the initial state probability vector at initial time t_0 , $0 \leq t_0 < t$. If, in particular, the analysis commences from an initial time in which the system is in a state with all components operational, then the initial state probability vector is $\Pi_0 = [1, 0, \dots, 0]^T$.

The transition rate matrix $Q(t) = [q_{ij}(t)]_{n \times n}$, $i, j \in I$, in (124) is a square matrix of order n , with the property that all of its off-diagonal components are positive and the component on the main diagonal is negative and equal with minus sum of all other elements on column, that is, $q_{ii}(t) = -\sum_{j=1, j \neq i}^n q_{ji}(t)$. The elements $q_{ij}(t)$ are considered to depend on the system's parameters $\alpha_k(t)$. The true values of these parameters are not known precisely in practice, but may vary according to some known distribution or (if this is unknown) within some limiting values (finite or infinite) that reflect the corresponding incomplete knowledge or uncertainty. The Kolmogorov system (124) becomes at steady state ($t \rightarrow t_\infty$)

$$Q(t_\infty) \Pi(t_\infty) = 0, \quad (126)$$

where $\Pi(t_\infty) \equiv [\pi_1(t_\infty), \pi_2(t_\infty), \dots, \pi_n(t_\infty)]^T$ represents the steady state probability vector at equilibrium (steady state) satisfying the relation $\sum_{i \in I} \pi_i = 1$ (conservation of probability).

Reliability of a component is defined as the probability that the component survives until some time t , considering that at a time t_0 the component was operating properly, $0 \leq t_0 \leq t \leq \infty$. Extended to a system, the *reliability* $R(t)$ of a physical system is the probability that the system is functional until a time t given that the system was operating correctly at an initial time t_0 . The definition of reliability implies that the system was not under repair until time t . In Markov

analysis for reliability quantification, the failure states of the system are considered absorbing states (defined as a state which the system never leaves after entering it), while the other states are considered to be transient states (defined as a state in which the system enters, exits, and never returns to it during its evolution) or recurrent states (defined as a state to which the system can return during its evolution.). The complementary function of reliability is called *unreliability*, $\bar{R}(t)$, of the system and is defined as $\bar{R}(t) \equiv 1 - R(t)$. The *availability*, $A(t)$, of a physical system is the probability that the system is operating correctly at a requested time t . The complementary function of availability is called *unavailability*, $\bar{A}(t)$, of the system and is defined as $\bar{A}(t) \equiv 1 - A(t)$. When computing the unavailability of a system, the failure states in the underlying Markov chain need not necessarily be absorbing states, since the system could have been repaired or components replaced during the time period from t_0 to t ; in such a case, the operational states could be either transient or recurrent states. Taking in account the properties of the states in Markov chain, the availability and reliability are computed in similar ways. Thus, if the states $I = \{1, 2, \dots\}$ of a Markov chain consists of a set of states in which the system is failed $\{Down\}$ and operational $\{Up\}$, then the transient solution of Kolmogorov equations gives the reliability/availability of the system as

$$R(t) = \sum_{i \in Up} \pi_i(t), \quad (127)$$

while the complementary function, the unreliability, is obtained as

$$\bar{R}(t) = \sum_{i \in Down} \pi_i(t) = 1 - R(t). \quad (128)$$

Recall that the instantaneous or point availability $A(t)$ of a component or a system is defined as the probability that the component or system is properly functioning at time t . In the absence of a repair or a replacement, the availability $A(t)$ is simply equal to the reliability $R(t)$ for a component. The instantaneous availability is always greater than or equal to the reliability. For a component, the instantaneous availability is

$$A(t) = \pi_i(t), \quad i \in \{Up\}. \quad (129)$$

The limiting or steady state availability is the limiting value of $A(t)$ as t approaches infinity, that is, $A = \lim_{t \rightarrow \infty} A(t) \neq 0$; this measure is usually nonzero, in contrast to limiting reliability which is always zero, that is, $R = \lim_{t \rightarrow \infty} R(t) = 0$. The average or interval availability represents the expected fraction of time the system is up in a given interval of time $[t_0, t]$, $0 \leq t_0 < t \leq \infty$, that is,

$$A_I \equiv \frac{1}{t_f} \int_{t_0}^{t_f} A(t) dt. \quad (130)$$

The repairing or replacing of a system component is characterized mathematically through transitions between states in the Markov chain representing the respective system. The failure behavior of components is determined statistically, and is consequently described by statistical distributions. The *failure (or hazard) rate* $\lambda(t)$ describes the expected number of failures in a given time period. The concepts of *mean time to failure* (MTTF), *mean time to repair* (MTTR), and *mean time between failures* ($MTBF \equiv MTTF + MTTR$) are also used for components and

systems. The mean time to repair is obtained from statistical considerations, but the mean time to failure can be computed in terms of the system's reliability as

$$MTTF = \int_{t_0}^{t_f} R(t) dt, \quad 0 \leq t_0 < t \leq \infty. \quad (131)$$

All of the system responses (i.e., reliability measures) defined in (127–131) are functionals of the transient probabilities $\pi_i(t)$, $i = 1, \dots, n$, and the elements $q_{ij}(t)$ of the transition rate matrix, which can in turn depend on external parameters, denoted in the sequel as $\alpha_k(t)$, that is, $q_{ij}(t) = f(\alpha_k(t))$, for $i, j = 1, \dots, n$; $k = 1, \dots, m$. Thus, all of these responses can be represented mathematically in the general form

$$R(\Pi(t), \alpha) \equiv \int_{t_0}^{t_f} F(\Pi(t), \alpha) dt, \quad 0 \leq t_0 < t, \quad (132)$$

where n denotes the number of states in Markov chain, m denotes the number of system parameters, t_0 and t_f represent the initial and, respectively, the final time under consideration, and $F(\pi_i; \alpha_k; t)$ represents a (possibly nonlinear) function of the indicated arguments.

As previously mentioned, the true values of the parameters α are not known in practice; usually, only their nominal (mean) values $\alpha^0 = (\alpha_1^0(t), \dots, \alpha_m^0(t))$ and their uncertainties $\delta\alpha \equiv (\delta\alpha_1, \dots, \delta\alpha_m)$ (variation intervals, bounds, or variance-covariances) are known. Hence, the Kolmogorov equations (124) can be solved using the nominal values $\{\alpha_1^0(t), \dots, \alpha_m^0(t)\}$ together with the nominal initial probability vector, $\Pi^0(t_0) = [\pi_1^0(t_0), \dots, \pi_n^0(t_0)]^T$, to obtain the nominal solution $\Pi^0(t)$ which is used, in turn, to obtain the base case response value $R^0(\Pi^0, \alpha^0)$. Note that the superscript “zero” is used throughout this work to denote base-case (i.e., nominal) values.

The typical deterministic approach for computing sensitivities for Markov chains is to solve the original system for the base case together with a larger set of differential equations for the respective sensitivities (see, e.g., Cao and Wan 1998; Ou and Dugan 2003). This set can be represented compact in matrix form as follows:

$$\begin{cases} \left[\frac{d}{dt} [\Pi^0(t)]_{n \times 1}, \frac{\partial}{\partial \alpha_k} \left(\frac{d}{dt} [\Pi^0(t)]_{n \times 1} \right) \right] \\ = \begin{bmatrix} [Q^0(t)]_{n \times n} & [0]_{n \times n} \\ \frac{\partial}{\partial \alpha_k} [Q^0(t)]_{n \times n} & [Q^0(t)]_{n \times n} \end{bmatrix} \begin{bmatrix} [\Pi^0(t)]_{n \times 1} \\ \frac{\partial}{\partial \alpha_k} [\Pi^0(t)]_{n \times 1} \end{bmatrix} \\ \left[[\Pi^0(t_0)]_{n \times 1}, \frac{\partial}{\partial \alpha_k} [\Pi^0(t_0)]_{n \times 1} \right] = \left[[\Pi_0]_{n \times 1}, \frac{\partial}{\partial \alpha_k} [\Pi_0]_{n \times 1} \right], \quad k = 1, \dots, m, \end{cases} \quad (133)$$

where the vector/matrix subscripts indicate the sizes of the respective vectors and matrices. In principle, the above equations can be solved repeatedly to obtain the functions $(\partial/\partial \alpha_k)[\Pi^0(t)]_{n \times 1}$. Subsequently, these functions can be used to compute the first-order effects of parameter variations $\delta\alpha_k$ on the response R . Since the set of differential equations need to be solved anew for each parameter variation $\delta\alpha_k$, this procedure is just as expensive as recalculating the perturbed response $R(\Pi^0 + \Phi, \alpha^0 + \delta\alpha^0)$ after having repeatedly solved the Kolmogorov system (124).

The need for solving repeatedly the system (133) can be avoided by applying the ASAP to the Kolmogorov system (124) and response (132), as generally shown in ► Sect. 4.3. The first step to compute the G-differential of the response (132) to obtain

$$\begin{aligned} DR(\Pi^0, \alpha^0; \Phi, \delta\alpha) &\equiv \frac{d}{d\varepsilon} \left\{ \int_{t_0}^{t_f} F(\Pi^0 + \varepsilon\Phi, \alpha^0 + \varepsilon\delta\alpha) \right\}_{\varepsilon=0} \\ &= \sum_{k=1}^m \int_{t_0}^{t_f} \left(\frac{\partial F}{\partial \alpha_k} \right)_{(\Pi^0, \alpha^0)} \delta\alpha_k dt + \int_{t_0}^{t_f} \left(\frac{\partial F}{\partial \Pi} \right)_{(\Pi^0, \alpha^0)}^T \Phi(t) dt \\ &\triangleq R'_\alpha(\Pi^0, \alpha^0) \delta\alpha + R'_\Pi(\Pi^0, \alpha^0) \Phi, \end{aligned} \quad (134)$$

where Φ denotes the vector of variations in Π (due to parameter variations $\delta\alpha$), $\partial F/\partial \Pi \equiv (\partial F/\partial \pi_1, \dots, \partial F/\partial \pi_n)^T$, and where

$$R'_\alpha(\Pi^0, \alpha^0) \delta\alpha \equiv \sum_{k=1}^m \int_{t_0}^{t_f} \left(\frac{\partial F}{\partial \alpha_k} \right)_{(\Pi^0, \alpha^0)} \delta\alpha_k dt \quad (135)$$

is the so-called “direct effect” term, while

$$R'_\Pi(\Pi^0, \alpha^0) \Phi \equiv \sum_{k=1}^m \int_{t_0}^{t_f} \left(\frac{\partial F}{\partial \Pi} \right)_{(\Pi^0, \alpha^0)}^T \Phi(t) dt \quad (136)$$

is the so-called “indirect effect” term, which can only be computed after having determined the functions $\Phi(t)$. Recall that

$$R(\Pi^0 + \Phi; \alpha^0 + \delta\alpha) = R(\Pi^0, \alpha^0) + DR(\Pi^0, \alpha^0; \Phi, \delta\alpha) + O(\|\Phi\|^2 + \|\delta\alpha\|^2),$$

indicating that the exact value of the perturbed response using recalculations is predicted by the sensitivity $DR(\Pi^0, \alpha^0; \Phi, \delta\alpha)$ to first-order accuracy in $\|\Phi\|^2$ and $\|\delta\alpha\|^2$, respectively.

The next step is to derive the forward sensitivity system [cf. (78) and (79)] by computing the G-differential to the Kolmogorov equations (124), to obtain

$$\begin{cases} L\Phi(t) = [\delta Q] \Pi^0(t); & L \equiv \frac{d}{dt} I - Q^0(t) \\ \Phi(t_0) = \Phi_0. \end{cases} \quad (137)$$

The final step is to construct the system adjoint to (137), by following the general procedure that lead to (85). For the particular case of (137), the required inner product between two vector valued functions $f(x) \equiv [f_1(x), \dots, f_n(x)]^T$, $g(x) \equiv [g_1(x), \dots, g_n(x)]^T$ is

$$\langle f(t), g(t) \rangle \equiv \sum_{i=1}^n \int_{t_0}^{t_f} [f(x)]^T [g(x)] dx. \quad (138)$$

Forming thus the inner product of (137) with a vector $\Psi(t) \equiv [\psi_1(t), \dots, \psi_n(t)]^T$ yields

$$\int_{t_0}^{t_f} \Psi^T(t) \left(\frac{d}{dt} I - Q^0 \right) \Phi(t) dt = \int_{t_0}^{t_f} \Psi^T(t) [\delta Q] \Pi^0(t) dt. \quad (139)$$

Performing the integration by parts on the left side of the above equation in order to transfer all the differentiation operations from the vector $\Phi(t)$ to the vector $\Psi(t)$ gives

$$\int_{t_0}^{t_f} \Psi^T(t) \left(\frac{d}{dt} I - Q^0 \right) \Phi(t) dt = \langle L^* \Psi, \Phi \rangle + \Psi^T(t_f) \Phi(t_f) - \Psi^T(t_0) \Phi(t_0), \quad (140)$$

where

$$L^*(.) = \left(-\frac{d}{dt} I - [Q^0(t)]^T \right) (.) \quad (141)$$

is the operator formally adjoint to the operator L . The construction of the adjoint sensitivity system can now be completed in two steps, as follows: (1) requiring that the first term on the right side of (140) represent the same functional as the “indirect-effect term” (136); and (2) eliminating the unknown value $\Phi(t_f)$ by requiring that $\Psi^T(t_f) = 0$. Following these two steps yields the adjoint sensitivity system

$$\left(-\frac{d}{dt} I - [Q^0(t)]^T \right) \Psi(t) = \left(\frac{\partial F}{\partial \Pi} \right)_{(\Pi^0, \alpha^0)}; \Psi(t_f) = 0, \quad (142)$$

and the following alternative expression for the response sensitivities in terms of the adjoint function $\Phi(t)$:

$$\begin{aligned} DR(\Pi^0, \alpha^0; \Phi, \delta\alpha) &= \int_{t_0}^{t_f} \Psi^T(t) [\delta Q] \Pi^0(t) dt + \Psi^T(t_0) \Phi(t_0) \\ &+ \sum_{k=1}^m \int_{t_0}^{t_f} \left(\frac{\partial F}{\partial \alpha_k} \right)_{(\Pi^0, \alpha^0)} \delta\alpha_k dt. \end{aligned} \quad (143)$$

Note that the adjoint sensitivity system (142) is linear in the adjoint function Ψ , depending on the response R , and is independent of parameter variations $\delta\alpha$. Hence, this system needs to be solved only once per response to obtain the adjoint function Ψ . In turn, Ψ is used in the integrand in (143) for computing efficiently the response sensitivities to all system parameters. Since the Kolmogorov system (124) are linear in Π , the adjoint sensitivity system can be solved independently of the base-case solution Π^0 , as expected.

The Kolmogorov system (124), the forward sensitivity system (137), and the adjoint sensitivity system (142) are all linear systems of ordinary differential equation which can be written generically in the form

$$\frac{dy_i}{dt} = f_i(t, y_1, \dots, y_n); \quad y_i(t_0) = y_{i_0}, \quad i = 1, \dots, n, \quad (144)$$

and can therefore be solved efficiently and accurately using, for example, the VODPK solver developed in Brown et al. (1989) and Brown and Hindmarsh (1989) together with incomplete LU-factorization for preconditioning (Rauzy 2004).

The implementation of the ASAP for sensitivity analysis of dynamic reliability of systems modeled by Markov chains comprises the following steps:

1. Abstraction of the physical system to construct fault tree diagrams;
2. Qualitative analysis of these fault trees for determining the generic fault states and minimal cut-sets;
3. Use of fault trees to construct the corresponding Markov chain;

4. Construction of the adjoint sensitivity system;
5. Solution of the resulting Kolmogorov differential equations, and of the adjoint system;
6. Use of adjoint functions to compute sensitivities of reliability measures to parameters;
7. Use of sensitivities.

The above steps have been implemented (Cacuci et al. 2008) in a computer software package comprising three interconnected modules, called QUEFT (qualitative evaluator for fault tree), MARKOMAG-S (Markov chain matrix generator and solver), and MCADJSEN (Markov chain adjoint sensitivity module). This computer software package has been used to perform a sensitivity and uncertainty analysis of the dynamic reliability of the international fusion material irradiation facility (IFMIF). This facility is projected (IFMIF-CDA Team; Martone 1996) to provide the necessary irradiation field for testing new materials and for generating a database for the behavior of materials under irradiation by 14-MeV neutron-fields, as would be expected during the operation of future fusion power reactors. The IFMIF facility comprises five main subsystems: test facilities, target facilities, accelerator facilities, conventional facilities, and the central control and common instrumentation subsystem, respectively. Reliability studies (IFMIF-CDA Team; Martone 1996) have indicated that these subsystems would need to fulfill a minimum total availability of 80.7% for the overall IFMIF. Furthermore, these studies have also indicated that, of all five IFMIF-subsystems, the IFMIF-accelerator system has the lowest availability, namely 88%. This accelerator-system for IFMIF has not been built yet, so the availability value of 88% was computed (IFMIF-CDA Team; Martone 1996) using fault-tree methods for the main accelerator subsystems. The data for the various components comprising the accelerator system were obtained from components of existing accelerator facilities, for a mission time of 168 h (7 days), which is considered to be the period of time between two scheduled maintenance operations. Furthermore, the availability value of 88% was obtained without taking into account any uncertainties. Since time-dependent changes are likely to occur (e.g., due to maintenance, repair, or replacement considerations in order to minimize the expenses for building and operating the accelerator facility) before commencing the actual construction of the accelerator facility, sensitivities and uncertainty studies must be performed in order to assess the influence of reliabilities of the various components on the overall accelerator system availability and reliability.

A simplified representation (Piaszczyk 1996) of the accelerator system is presented in ▶ Fig. 1, while ▶ Fig. 2 depicts the fault tree of (only) the first level of the accelerator system. The associated Markov chain comprises 32 coupled differential equations corresponding to the transitions shown in ▶ Fig. 3. The corresponding transition rate matrix is sparse, containing just 193 nonzero elements; its structure is shown in ▶ Fig. 4.

▶ Table 2 presents results for the sensitivities of the average (or interval) availability response to the initial state probability vector, while ▶ Table 3 presents sensitivities of the same response to the system parameters (failure and repair rates), for the first-level fault tree of the accelerator system. The average (or interval) availability response is represented mathematically as the integral $R = (1/t_f) \int_{t_0}^{t_f} \pi_1(t) dt$; this type of response produces a source term of form $\partial F / \partial \Pi = [1, 0, \dots, 0]^T$ in adjoint sensitivity system, for all time steps until the final mission time at $t_f = 168$ h [cf. (142)]. The results presented in ▶ Table 2 show that the response depends linearly on the initial conditions, and the ASAP computes the respective sensitivities very accurately. On the other hand, the comparisons between the exact recalculations and the corresponding ASAP results presented in ▶ Table 3 indicate that the response depends nonlinearly on the respective failure and repair rates.

The magnitudes of the relative sensitivities of the average availability $R = (1/t_f) \int_{t_0}^{t_f} \pi_1(t) dt$ to the *MTTFs* and *MTTRs* of over 180 components of the IFMIF accelerator system are presented in Cacuci et al. (2008). The importance ranking of these components for the average availability response is depicted in Fig. 5, which indicates that the highest sensitivities of the average availability of the IFMIF accelerator systems are, in order, to the LINAC-RF-parameters, followed by the LINAC-parameters, HEBT-parameters, INJECTOR-parameters, and the COOLING-system parameters.

Another important response for the IFMIF accelerator system facilities is the system's availability at the final mission time of $t_f = 168$ h (7 days). In this case, the mathematical representation of the system response is $R = \int_{t_0}^{t_f} \pi_1(\mathbf{t})\delta(\mathbf{t} - \mathbf{t}_f)d\mathbf{t} = \pi_1(\mathbf{t}_f)$, where the symbol δ represents the Dirac-delta functional, and where the initial time has been taken as $t_0 = 0$. This response gives rise to a source term in the adjoint sensitivity equations [cf. (142)] of the form $\partial F/\partial \Pi = [1, 0, \dots, 0]^T$ at the end of mission time $t_f = 168$ h, and $\partial F/\partial \Pi = [0, 0, \dots, 0]^T$ for all other time steps. The results of the sensitivity analysis for this response are summarized pictorially in  Fig. 6, which presents the importance ranking of the IFMIF accelerator system

components based on the sensitivities of the *final-time availability* response to the components’ *MTTFs* and *MTTRs*. The results show that, although the importance ranking is generally the same (within the subsystems) as it was for the “average availability” response, the overall importance of the subsystems to the accelerator facility is changed, in that the LINAC and RF system have changed places, with the LINAC-sensitivities now displaying the largest absolute values. In other words, the reliability of the LINAC-components is the most important factor for the final-time availability of the overall IFMIF-accelerator, but the reliability of the RF-components is the most important factor for the average reliability of the overall IFMIF-accelerator. The complete sensitivity analysis, including numerical results for the sensitivities of

the “final-time availability” response to the over 180 IFMIF-system parameters are presented in Cacuci et al. (2008).

4.5 Global Optimization and Sensitivity Analysis

As discussed in ► Sect. 4.4, the scope of local sensitivity analysis is to calculate exactly and efficiently the sensitivities of the system’s response to variations in the system’s parameters, around their nominal values. As has also been shown in those chapters, the sensitivities are given by the first Gâteaux-differential of the system’s response, calculated at the nominal value of the system’s dependent variables (i.e., state functions) and parameters. Two procedures were presented for calculating the local sensitivities exactly, namely, the *forward sensitivity analysis procedure* (FSAP) and the *adjoint sensitivity analysis procedure* (ASAP). Among other uses, these sensitivities provide the first-order changes in the response due to parameter variations. However, the contributions from the higher-order terms in $\|\delta \alpha\|$ would require knowledge of the higher-order Gâteaux-differentials of the response and of the operator equations underlying the mathematical description of the physical system under investigation, since, as is well known, the Taylor series of a general operator reads

$$\begin{aligned}
 F(x_0 + h) = & F(x_0) + \delta F(x_0; h) + \frac{1}{2} \delta^2 F(x_0; h) + \cdots + \frac{1}{(n-1)!} \delta^{n-1} F(x_0; h) \\
 & + \int_0^1 \frac{(1-t)^{n-1}}{(n-1)!} \delta^n F(x_0 + th; h) dt,
 \end{aligned} \tag{145}$$

Although several techniques have been proposed (see, e.g., IFMIF-CDA Team; Martone 1996) for calculating the higher-order response derivatives with respect to the system’s parameters, none has proven routinely practicable for large-scale problems. This is because the systems

of equations that need to be solved for obtaining the second (and higher) order Gâteaux-differentials of the response and system's operator equations are very large and depend on the perturbation $\delta\alpha$. Thus, even the calculation of the second-order Gâteaux-differentials of the response and system's operator equations is just as difficult as undertaking the complete task of computing the exact value of perturbed response $R(\alpha_1^0 + \delta\alpha_1, \dots, \alpha_k^0 + \delta\alpha_k)$.

As is well known, *the Taylor series is a local concept, valid within some radius of convergence of the series around the base-case value x_0* . This means that even if the Gâteaux-differentials of the response $R(\alpha)$ around α^0 were, in theory, available to all orders, they would still merely provide local, but not global, information. They would yield little, if any, information about the important global features of the physical system, namely, the critical points of $R(\alpha)$ and the bifurcation branches and/or turning points of the system's state variables. In practice, of course, it is very difficult, if not impossible, to calculate the requisite higher-order Gâteaux-differentials for large-scale systems with many parameters.

As mentioned in [Sect. 4](#), an alternative to computing higher order response derivatives has been presented in Kramer et al. (1984), which proposed the so-called *feature sensitivity analysis* method for nonlinearly probing a larger region in the parameter-space. This method considers that the response $R(r, t; \alpha)$ can be written in the equivalent form $R(r, t; \alpha + \Delta\alpha) \equiv P[r, t; \beta(\alpha + \Delta\alpha)]$, where $\beta(\alpha) \equiv (\beta_1, \beta_2, \dots)$ is a vector whose components are the "feature" parameters, and where the form of $P[r, t; \beta(\alpha + \Delta\alpha)]$ is assumed to be explicitly known. In such a case, it is possible to consider the linear expansion $\beta(\alpha + \Delta\alpha) \cong \beta(\alpha) + \Delta\alpha \partial\beta/\partial\alpha$, which can be substituted in the expression of $R(r, t; \alpha + \Delta\alpha)$ to obtain a nonlinear scaling expression with respect to the parameters $\Delta\alpha$. This way, it is possible to enlarge (somewhat) the investigation of the response to a larger neighborhood of the nominal parameter values α_k^0 . Nevertheless, the feature sensitivity analysis method is not a genuinely global method, since it cannot compute critical points (e.g., bifurcations, extrema) globally.

A genuinely global method has been proposed in the original work (Cacuci 1990) for determining, with probability one, all of the system's critical points (bifurcations, turning points, response extrema) in the combined phase space formed by the parameters, state variables, and adjoint variables, and subsequently analyze these critical points by local sensitivity analysis. The salient features of this global method will be presented in the sequel, by considering that the mathematical model of the physical system and associated responses has been discretized as would be required prior to numerical computations. This description in terms of algebraic (as opposed to differential and/or integral) operators in finite dimensional vector spaces simplifies considerably the mathematical manipulations to follow without detracting from the conceptual generality and applicability of the underlying methodology. In the sequel, all vectors are considered to be column vectors, while the superscript T will be used to denote transposition.

The canonical discretized mathematical representation of the physical system under consideration comprises:

1. m linear and/or nonlinear equations represented in operator form as:

$$N(\varphi, \alpha) = 0, \quad N \equiv [N_1(\varphi, \alpha), \dots, N_m(\varphi, \alpha)] : D_N \subset D_\varphi \times \mathbb{R}^i \rightarrow \mathbb{R}^m, \quad (146)$$

where each algebraic operator component $N_m(\varphi, \alpha)$ is considered to act nonlinearly on the vector of system parameters $\alpha \equiv (\alpha_1, \dots, \alpha_i)$, $\alpha \in \mathbb{R}^i$, and on the vector of state functions $\varphi \equiv (\varphi_1, \dots, \varphi_m)$, $\varphi : D_\varphi \subset \mathbb{R}^m$. Note that the components of both α and φ are considered here to be scalar quantities, taking on values in the real Euclidean spaces $\mathbb{R}^i$ and $\mathbb{R}^m$, respectively. Since (146) is a canonical representation for problems that have been fully discretized in

preparation for a numerical solution, it automatically comprises all initial and/or boundary conditions which may have appeared in the originally continuous-variable description of the physical problem.

2. k inequality and/or equality constraints:

$$g(\alpha) \leq 0, \quad g(\alpha) \equiv [g_1(\alpha), \dots, g_k(\alpha)] : D_g \subset \mathbb{R}^i \rightarrow \mathbb{R}^k, \quad (147)$$

where $\mathbf{g}(\alpha) \equiv [g_1(\alpha), \dots, g_k(\alpha)]$ is a k -component column vector, defined on a domain D_g that delimits, directly or indirectly, the range of the parameters α_i .

3. A system response, $R(\varphi, \alpha)$, considered to be a real-valued functional of φ and α , defined on a domain D_P and having its range in $\mathbb{R}^1$, that is,

$$R(\varphi, \alpha), \quad R(\varphi, \alpha) : D_P \subset D_\varphi \times \mathbb{R}^i \rightarrow \mathbb{R}^1. \quad (148)$$

4.5.1 Critical Points and Global Optimization

The fundamental problem of global optimization is to find the points that minimize or maximize the system response $R(\varphi, \alpha)$ subject to the equality and inequality constraints represented by (146) and (147). This problem is typically handled by introducing the Lagrange functional, $L(\varphi, y, \alpha, z)$, defined as

$$L(\varphi, y, \alpha, z) \equiv R(\varphi, \alpha) + \langle y, N(\varphi, \alpha) \rangle_m + \langle z, g(\alpha) \rangle_k, \quad (149)$$

where the angular brackets denote inner products in $\mathbb{R}^m$ and $\mathbb{R}^k$, respectively; that is,

$$\langle a, b \rangle_n = a \bullet b = \sum_{i=1}^n a_i b_i; \quad a, b \in^n; (n = m \text{ or } k), \quad (150)$$

while $y = (y_1, \dots, y_m)$ and $z = (z_1, \dots, z_k)$ are column vectors of Lagrange multipliers. The critical points (i.e., extrema) of R are found among the points that cause the first Gâteaux-variation δL of L to vanish for arbitrary variations $\delta\varphi$, δy , δz , and $\delta\alpha$.

From (149), δL is obtained as

$$\delta L(\varphi, y, \alpha, z) = \langle \delta\varphi, N^+(\varphi, y, \alpha) \rangle + \langle \delta y, N(\varphi, \alpha) \rangle + \langle \delta z, g(\alpha) \rangle + \langle \delta\alpha, S(\varphi, y, \alpha, z) \rangle, \quad (151)$$

where the column vectors N^+ and S are defined as

$$N^+(\varphi, y, \alpha) \equiv \nabla_\varphi R + (\nabla_\varphi N) y, \quad (152)$$

$$S(\varphi, y, \alpha, z) \equiv \nabla_\alpha R + (\nabla_\alpha N) y + (\nabla_\alpha g) z. \quad (153)$$

The gradient vectors and matrices appearing in (152) and (153) are defined as follows:

$$\nabla_\varphi R \equiv \left(\partial R / \partial \varphi_p \right)_{m \times 1}, \quad \nabla_\alpha R \equiv (\partial R / \partial \alpha_q)_{i \times 1}, \quad (154)$$

$$\nabla_\varphi N \equiv \left(\partial N_r / \partial \varphi_p \right)_{m \times m}, \quad \nabla_\alpha N \equiv (\partial N_r / \partial \alpha_q)_{i \times m}, \quad (155)$$

$$\nabla g \equiv (\partial g_s / \partial \alpha_q)_{i \times k}. \quad (156)$$

The requirements that the first Gâteaux-variation δL of L vanish, for arbitrary $\delta\varphi, \delta y, \delta z$, and $\delta\alpha$, together with the constraints $\mathbf{g} \leq \mathbf{0}$, lead to the following necessary conditions:

$$\begin{aligned} N^+(\varphi, y, \alpha) &= \mathbf{0}, & S(\varphi, y, \alpha, z) &= \mathbf{0}, \\ N(\varphi, \alpha) &= \mathbf{0}, \langle z, \mathbf{g} \rangle &= \mathbf{0}, & \mathbf{g} \leq \mathbf{0}, \quad z \geq \mathbf{0}, \end{aligned} \quad (157)$$

for the minima of $R(\varphi, \alpha)$ and similar conditions (except that $\mathbf{z} \leq \mathbf{0}$) for the maxima of $R(\varphi, \alpha)$. The inequalities in (157) imply a lack of global differentiability, so a direct solution is usually hampered by computational difficulties. Such computational difficulties can be mitigated by recasting the last three conditions in (157) into the following equivalent form which involves equalities only:

$$K \equiv (K_1, \dots, K_k) = \mathbf{0}, \quad K_i \equiv (g_i + z_i)^2 + g_i |g_i| - z_i |z_i|. \quad (158)$$

Using (158) in (157) makes it possible to recast the latter into the equivalent form

$$\mathbf{F}(\mathbf{u}) \equiv [N^+(\mathbf{u}), N(\mathbf{u}), S(\mathbf{u}), K(\mathbf{u})] = \mathbf{0}, \quad \mathbf{u} \equiv (\varphi, y, \alpha, z), \quad \mathbf{u} \in \mathbb{R}^{2m+i+k}, \quad (159)$$

where the components of the column vector $\mathbf{u}$ are, respectively: the dependent variables, φ ; their corresponding Lagrange multipliers, y ; the parameters, α ; and the Lagrange multipliers, z , corresponding to the inequalities constraints, $\mathbf{g}$.

As will be shown in the sequel, choosing the above structure of $\mathbf{F}$ allows considerable simplifications in the global numerical procedure to be devised for finding the roots and critical points of (159). It is important to note that $\mathbf{F}$ is globally differentiable if R, N , and $\mathbf{g}$ are differentiable twice globally. The Jacobian matrix $\mathbf{F}'(\mathbf{u})$ of $\mathbf{F}(\mathbf{u})$ has the block matrix structure

$$\mathbf{F}'(\mathbf{u}) = \begin{bmatrix} \nabla_{\varphi} N^+ & \nabla_{\varphi} N & \nabla_{\varphi} S & \mathbf{0} & \mathbf{0} \\ (\nabla_{\varphi} N)^T & \mathbf{0} & (\nabla_{\alpha} N)^T & \mathbf{0} & \mathbf{0} \\ (\nabla_{\varphi} S)^T & \nabla_{\alpha} N & \nabla_{\alpha} S & \nabla \mathbf{g}_A & \nabla \mathbf{g}_I \\ \mathbf{0} & \mathbf{0} & 2\mathbf{Z}_A (\nabla \mathbf{g}_A)^T & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & 2\mathbf{C}_I \end{bmatrix}, \quad (160)$$

where $A \equiv \{j | g_j = 0\}$ and $I \equiv \{j | g_j < 0\}$ denote the set of indices corresponding to the active and inactive constraints, respectively, while the remaining quantities are defined as follows:

$$\nabla_{\varphi} N^+ \equiv \left[\partial^2 R / \partial \varphi_p \partial \varphi_r + \langle y, \partial^2 N / \partial \varphi_p \partial \varphi_r \rangle_m \right]_{m \times m}, \quad (161)$$

$$\nabla_{\varphi} S \equiv \left[\partial^2 R / \partial \varphi_p \partial \alpha_q + \langle y, \partial^2 N / \partial \varphi_p \partial \alpha_q \rangle_m \right]_{m \times i}, \quad (162)$$

$$\nabla_{\alpha} S \equiv \left[\partial^2 R / \partial \alpha_q \partial \alpha_r + \langle y, \partial^2 N / \partial \alpha_q \partial \alpha_r \rangle_m + \langle z, \partial^2 g / \partial \alpha_q \partial \alpha_r \rangle_k \right]_{i \times i}, \quad (163)$$

$$\nabla \mathbf{g}_A \equiv (\partial g_j / \partial \alpha_q)_{(j \in A) \times i}, \quad \mathbf{Z}_A \equiv \text{diag}(z_j)_{j \in A}, \quad (164)$$

$$\nabla \mathbf{g}_I \equiv (\partial g_j / \partial \alpha_q)_{(j \in I) \times i}, \quad \mathbf{C}_I \equiv \text{diag}(g_j)_{j \in I}. \quad (165)$$

By introducing the equivalence (157) $\Leftrightarrow$ (159), all inequalities have disappeared from $\mathbf{F}(\mathbf{u}) = \mathbf{0}$. Furthermore, the Jacobian $\mathbf{F}'(\mathbf{u})$ is nonsingular at the zeros of $\mathbf{F}(\mathbf{u})$, so efficient numerical methods, such as locally superlinearly convergent quasi-Newton methods, can be used to find

these zeros. Note that in the two extreme situations when the constraints are either all inactive or all active, the matrices $\nabla \mathbf{g}_A$ and $2\mathbf{Z}_A (\nabla \mathbf{g}_A)^T$ or the matrices $\nabla \mathbf{g}_I$ and $\mathbf{C}_I$ disappear, respectively, from the structure of $\mathbf{F}'(\mathbf{u})$. The Jacobian $\mathbf{F}'(\mathbf{u})$ vanishes, though, at the bifurcation and limit and/or turning points present in our system. Such critical points need to be located by using global methods (as will be presented in ► Sect. 4.5.3) that are capable of avoiding local non-convergence problems.

4.5.2 Sensitivity Analysis

The fundamental problem in sensitivity analysis is to determine the effects caused by variations $\delta \alpha$ around nominal parameter values α^0 in the response $R(\varphi, \alpha)$, subject to the constraints represented by (146) and (147). Within the framework of sensitivity analysis, therefore, both α^0 and $\delta \alpha$ are known, at the outset, and variations $\delta \alpha$ around α^0 induce variations in the response that can be computed, to first order, from the Taylor series

$$\begin{aligned} \Delta R(\varphi^0, \alpha^0) &\equiv R(\varphi, \alpha) - R(\varphi^0, \alpha^0) \\ &= \left\langle \delta \alpha, \{\nabla_{\alpha} R\}_{(\varphi^0, \alpha^0)} \right\rangle + \left\langle \delta \varphi, \{\nabla_{\varphi} R\}_{(\varphi^0, \alpha^0)} \right\rangle + O(\|\Delta \alpha\|^2, \|\Delta \varphi\|^2). \end{aligned} \quad (166)$$

The above expression explicitly indicates the important fact that the respective gradients are to be evaluated at the nominal values α^0 and $\varphi^0 = \varphi(\alpha^0)$, obtained from the solution of $N(\varphi^0, \alpha^0) = \mathbf{0}$. As shown in ► Sect. 4.4, the variations $\delta \varphi$ and $\delta \alpha$ in (166) are not independent, but are related to each other through the relationship

$$\begin{bmatrix} \left\{ (\nabla_{\varphi} N)^T \right\}_{(\varphi^0, \alpha^0)} & \left\{ (\nabla_{\alpha} N)^T \right\}_{(\varphi^0, \alpha^0)} \\ 0 & \left\{ (\nabla_{\alpha} \mathbf{g})^T \right\}_{(\varphi^0, \alpha^0)} \end{bmatrix} \begin{pmatrix} \delta \varphi \\ \delta \alpha \end{pmatrix} = O(\|\Delta \alpha\|^2, \|\Delta \varphi\|^2), \quad (167)$$

which are obtained by taking Gâteaux-differentials of (146) and (147), respectively. Forming the inner product of (167) with the partitioned vector $(\mathbf{y}, \mathbf{z})$, and transposing the resulting expression (which corresponds to determining the respective adjoint operators and functions in the continuous-variable case) yields

$$\left\langle \delta \varphi, \{\nabla_{\varphi} N\}_{(\varphi^0, \alpha^0)} \mathbf{y} \right\rangle + \left\langle \delta \alpha, \{\nabla_{\alpha} N\}_{(\varphi^0, \alpha^0)} \mathbf{y} + \{\nabla_{\alpha} \mathbf{g}\}_{(\varphi^0, \alpha^0)} \mathbf{z} \right\rangle = O(\|\Delta \alpha\|^2, \|\Delta \varphi\|^2). \quad (168)$$

Requiring next that the Lagrange multipliers (which are actually the adjoint functions) $\mathbf{y}^0$ be the solutions of the adjoint equations,

$$\{\nabla_{\varphi} N\}_{(\varphi^0, \alpha^0)} \mathbf{y}^0 + \{\nabla_{\varphi} R\}_{(\varphi^0, \alpha^0)} = \mathbf{0}, \quad (169)$$

and using their resulting expressions in (168) gives

$$\left\langle \delta \varphi, \{\nabla_{\varphi} R\}_{(\varphi^0, \alpha^0)} \right\rangle = \left\langle \delta \alpha, \{\nabla_{\alpha} N\}_{(\varphi^0, \alpha^0)} \mathbf{y}^0 + \{\nabla_{\alpha} \mathbf{g}\}_{(\varphi^0, \alpha^0)} \mathbf{z}^0 \right\rangle + O(\|\Delta \alpha\|^2, \|\Delta \varphi\|^2). \quad (170)$$

Finally, replacing (4.103) in (4.99) gives

$$\Delta R(\varphi^0, \alpha^0) = \delta \alpha \bullet \mathbf{S}(\varphi^0, \mathbf{y}^0, \alpha^0, \mathbf{z}^0) + O(\|\Delta \alpha\|^2, \|\Delta \varphi\|^2), \quad (171)$$

where the components of the vector $\mathbf{S}(\boldsymbol{\varphi}^0, \mathbf{y}^0, \boldsymbol{\alpha}^0, \mathbf{z}^0)$, defined as

$$\mathbf{S}(\boldsymbol{\varphi}^0, \mathbf{y}^0, \boldsymbol{\alpha}^0, \mathbf{z}^0) \equiv \{\nabla_{\boldsymbol{\alpha}} R\}_{(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)} + \{\nabla_{\boldsymbol{\alpha}} \mathbf{N}\}_{(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)} \mathbf{y}^0 + \{\nabla_{\boldsymbol{\alpha}} \mathbf{g}\}_{(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)} \mathbf{z}^0, \quad (172)$$

contain the first-order sensitivities at $\boldsymbol{\alpha}^0$ of $R(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$ to variations $\delta\boldsymbol{\alpha}$, and where the adjoint variables $\mathbf{y}^0$ are the solutions of (169) while the Lagrange multipliers $\mathbf{z}$ are chosen such as to enforce the linear independence of the constraints, that is, $\langle \mathbf{z}, \mathbf{g} \rangle = 0$; note that the adjoint system is occasionally defined with $(-\mathbf{y}^0)$ replacing $\mathbf{y}^0$ in (169).

On the other hand, adopting a variational point of view, the sensitivity expression given by (172) can also be obtained by using the same Lagrange functional, L , as used in (149); recall that its first Gâteaux-variation, δL , has the form given in (151), which is repeated below for convenience:

$$\begin{aligned} \delta L(\boldsymbol{\varphi}, \mathbf{y}, \boldsymbol{\alpha}, \mathbf{z}) &= \langle \delta\boldsymbol{\varphi}, \nabla_{\boldsymbol{\varphi}} R + (\nabla_{\boldsymbol{\varphi}} \mathbf{N}) \mathbf{y} \rangle + \langle \delta\mathbf{y}, \mathbf{N}(\boldsymbol{\varphi}, \boldsymbol{\alpha}) \rangle \\ &\quad + \langle \delta\mathbf{z}, \mathbf{g}(\boldsymbol{\alpha}) \rangle + \langle \delta\boldsymbol{\alpha}, \nabla_{\boldsymbol{\alpha}} R + (\nabla_{\boldsymbol{\alpha}} \mathbf{N}) \mathbf{y} + (\nabla_{\boldsymbol{\alpha}} \mathbf{g}) \mathbf{z} \rangle. \end{aligned} \quad (151)$$

At this stage, it is important to note that, in contradistinction to the optimization framework, the parameter variations $\delta\boldsymbol{\alpha}$ are not arbitrary in sensitivity analysis, but are prescribed at the outset. Hence, imposing now the requirement that δL be stationary at $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$ with respect to arbitrary variations $\delta\boldsymbol{\varphi}$, $\delta\mathbf{y}$, $\delta\mathbf{z}$ (but not with respect to $\delta\boldsymbol{\alpha}$, since these variations are not arbitrary!) has the following consequences:

- (a) A stationary δL at $\boldsymbol{\alpha}^0$ with respect to $\delta\mathbf{y}$ implies that $\mathbf{N}(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0) = \mathbf{0}$, thereby fixing the nominal values $\boldsymbol{\varphi}^0$;
- (b) A stationary δL at $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$ with respect to $\delta\boldsymbol{\varphi}$ implies that the adjoint variables $\mathbf{y}^0$ must satisfy the adjoint Eq. (169) at $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$;
- (c) A stationary δL at $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$ with respect to $\delta\mathbf{z}$ ensures that the constraints $\mathbf{g}(\boldsymbol{\alpha}^0)$ are satisfied while fixing the values $\mathbf{z}^0$ of the Lagrange multipliers $\mathbf{z}$, and

$$\begin{aligned} \delta L(\boldsymbol{\varphi}^0, \mathbf{y}^0, \boldsymbol{\alpha}^0, \mathbf{z}^0) &= \langle \delta\boldsymbol{\alpha}, \{\nabla_{\boldsymbol{\alpha}} R\}_{(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)} + \{\nabla_{\boldsymbol{\alpha}} \mathbf{N}\}_{(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)} \mathbf{y}^0 + \{\nabla_{\boldsymbol{\alpha}} \mathbf{g}\}_{(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)} \mathbf{z}^0 \rangle \\ &= \delta\boldsymbol{\alpha} \bullet \mathbf{S}(\boldsymbol{\varphi}^0, \mathbf{y}^0, \boldsymbol{\alpha}^0, \mathbf{z}^0) \\ &= \Delta R(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0) + O(\|\Delta\boldsymbol{\alpha}\|^2, \|\Delta\boldsymbol{\varphi}\|^2), \end{aligned} \quad (173)$$

which is the same expression for the sensitivity ΔR of R at $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$ as was obtained in (171) via the Gateaux-differential approach of  Sect. 4.4 (as opposed to the variational approach in this section).

Even though both the optimization and sensitivity analysis frameworks use the first Gâteaux-variation $\delta L(\boldsymbol{\varphi}, \mathbf{y}, \boldsymbol{\alpha}, \mathbf{z})$ of the same formal Lagrangian functional $L(\boldsymbol{\varphi}, \mathbf{y}, \boldsymbol{\alpha}, \mathbf{z})$, there are fundamental conceptual differences between them. On the one hand, the sensitivity analysis framework revolves fundamentally around the *a priori known* nominal point $\boldsymbol{\alpha}^0$, and imposes on $\delta L(\boldsymbol{\varphi}, \mathbf{y}, \boldsymbol{\alpha}, \mathbf{z})$ the requirements that it be stationary at $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$ with respect to arbitrary variations $\delta\boldsymbol{\varphi}$, $\delta\mathbf{y}$, $\delta\mathbf{z}$, but not with respect to $\delta\boldsymbol{\alpha}$, since these variations are not arbitrary, as has been previously noted. On the other hand, the optimization theory framework for finding the critical points of $R(\boldsymbol{\varphi}, \boldsymbol{\alpha})$ imposes the requirements that (1) δL be stationary with respect to

$\delta \mathbf{y}$, implying that $N(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*) = \mathbf{0}$ at the *yet unknown critical point* $(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$; (2) δL be stationary with respect to $\delta \boldsymbol{\varphi}$, implying that $\mathbf{y}^*$ must satisfy at $(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$ the adjoint equation $N^+(\boldsymbol{\varphi}^*, \mathbf{y}^*, \boldsymbol{\alpha}^*) \equiv \{\nabla_{\boldsymbol{\varphi}} N\}_{(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)} \mathbf{y}^* + \{\nabla_{\boldsymbol{\varphi}} R\}_{(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)} = \mathbf{0}$; (3) δL be stationary with respect to $\delta \mathbf{z}$, implying that the respective constraints must be satisfied at the yet unknown critical point $(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$; and, *in contradistinction to the sensitivity analysis framework*, the requirement that (4) δL be stationary with respect to $\delta \boldsymbol{\alpha}$, implying that

$$S(\boldsymbol{\varphi}^*, \mathbf{y}^*, \boldsymbol{\alpha}^*, \mathbf{z}^*) \equiv \{\nabla_{\boldsymbol{\alpha}} P\}_{(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)} + \{\nabla_{\boldsymbol{\alpha}} N\}_{(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)} \mathbf{y}^* + \{\nabla_{\boldsymbol{\alpha}} \mathbf{g}\}_{(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)} \mathbf{z}^* = \mathbf{0} \quad (174)$$

at the critical point $(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$. Note that the critical point $(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$ is not *a priori* known, but is to be determined from the solution of (159). In other words, the foregoing conditions (1)–(4) constitute a system of $2m + i + k$ equations whose simultaneous solution yields the regular critical points $(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$ of $R(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$ together with the respective values $\mathbf{y}^*$ and $\mathbf{z}^*$ of the Lagrange multipliers. *Note the important fact that condition (4) above cannot be imposed within the framework of sensitivity analysis, since δL cannot be required to vanish for known variations $\delta \boldsymbol{\alpha}$ around a fixed, a priori known point $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$; δL will vanish for variations $\delta \boldsymbol{\alpha}$ only if the respective point $(\boldsymbol{\varphi}^0, \boldsymbol{\alpha}^0)$ happens to coincide with a regular critical point $(\boldsymbol{\varphi}^*, \boldsymbol{\alpha}^*)$.*

4.5.3 Global Computation of Fixed Points

The vector $\mathbf{F}(\mathbf{u})$ defined in (159) contains all the features necessary for performing both global optimization and sensitivity analysis. Setting to zero all *four* components of $\mathbf{F}(\mathbf{u})$, namely: $N(\mathbf{u})$, $N^+(\mathbf{u})$, $\mathbf{K}(\mathbf{u})$, and $\mathbf{S}(\mathbf{u})$, yields the respective critical points $\mathbf{u}^*$ that optimize the system response. On the other hand, setting only *three* components of $\mathbf{F}(\mathbf{u})$, that is, $N(\mathbf{u})$, $N^+(\mathbf{u})$, and $\mathbf{K}(\mathbf{u})$, to zero at *any* point $\mathbf{u}^0$ and calculating its fourth component $\mathbf{S}(\mathbf{u}^0)$ yields the first-order local sensitivities at $\mathbf{u}^0$. Of course, $\mathbf{S}(\mathbf{u}^0)$ would vanish if $\mathbf{u}^0$ happened to coincide with a critical point $\mathbf{u}^*$ of $R(\boldsymbol{\varphi}, \boldsymbol{\alpha})$. Devising a computational algorithm that could determine the features mentioned in the foregoing, over the global space of allowed parameter variations, would extend the scopes of both optimization and sensitivity analysis while unifying their underlying computational methodologies. Such a computational algorithm will be briefly described in the remainder of this section.

The initial information available in practical problems comprises the nominal design values $\boldsymbol{\alpha}^0$ of the problem's parameters $\boldsymbol{\alpha}$, and the ranges over which the respective parameters can vary, as expressed mathematically by the constraints in (147). As the parameters $\boldsymbol{\alpha}$ vary over their respective ranges, the state variables $\boldsymbol{\varphi}$ and the response R vary in phase space. The objective of the computational algorithm, therefore, is to determine all of the critical points where the solution path $\boldsymbol{\varphi}$ bifurcates (i.e., splits in two or more branches) and where the response R attains maxima, minima, and/or saddle points. The bifurcation points occur at the zeros of the determinant of the Jacobian matrix $\mathbf{F}'(\mathbf{u})$, denoted as $\text{Det}[\mathbf{F}'(\mathbf{u})]$, while the maxima, minima, and/or saddle points of R occur at the zeros of $\mathbf{F}(\mathbf{u})$, respectively.

To determine all the zeros of both $\mathbf{F}(\mathbf{u})$ and $\text{Det}[\mathbf{F}'(\mathbf{u})]$, it is essential to use an algorithm that embodies the following properties:

- Efficiently avoids non-convergence problems at the singularities of $\mathbf{F}'(\mathbf{u})$;
- Avoids getting bogged down (as many local methods do) at the first zero of $\mathbf{F}(\mathbf{u})$ that it may happen to find; and

- (c) Finds all the fixed points $\mathbf{u}_i^*$ of $\mathbf{F}(\mathbf{u})$ regardless of the starting point $\mathbf{u}_0$. It is apparent that local computational methods would not satisfy all these requirements; a global method would need to be devised for this purpose.

Perhaps the most powerful mathematical techniques for obtaining global results are the homotopy theory-based continuation methods. Typically, these methods compute the solution $\mathbf{u}^*$ of a fixed-point equation such as (159) by embedding it into a one-parameter family of equations of the form $\mathbf{G}(\mathbf{u}, \lambda) = \mathbf{0}$, where $\lambda \in \mathbb{R}^1$ is a real scalar. Most of the direct procedures to follow the path $\mathbf{u}(\lambda)$ typically encounter difficulties (slow convergence, small steps, or even failure) at points where the Fréchet-derivative $\mathbf{G}'_{\mathbf{u}}$ does not have a bounded inverse. Such difficulties can be efficiently circumvented by the “pseudo-arc-length” (i.e., distance along a local tangent) continuation methods, which employ a scalar constraint in addition to the homotopy $\mathbf{G}(\mathbf{u}, \lambda) = \mathbf{0}$, thus “inflating” the original problem into one of higher dimension.

To determine the roots of $\mathbf{F}(\mathbf{u}) = \mathbf{0}$ and $\mathbf{F}'(\mathbf{u}) = \mathbf{0}$ by means of the pseudo-arc-length continuation method, the homotopy $\mathbf{G}(\mathbf{u}, \lambda) = \mathbf{0}$ is specified to be of the form

$$\mathbf{G}(\mathbf{u}, \lambda) \equiv \mathbf{F}[\mathbf{u}(s)] - \lambda(s) \mathbf{F}(\mathbf{u}_0) = \mathbf{0}. \quad (175)$$

where $\mathbf{F}[\mathbf{u}(s)]$ is as defined in (159), while $\mathbf{u}_0$ denotes a fixed (e.g., starting) value of $\mathbf{u}$. Note that (175) implies that $\mathbf{u}(s)$ must satisfy the differential equation obtained by setting to zero its first Gâteaux-derivative with respect to s , namely,

$$\mathbf{F}'(\mathbf{u}) \mathbf{w}(s) + \mu(s) \mathbf{F}(\mathbf{u}_0) = \mathbf{0}. \quad (176)$$

In addition to the above homotopy, we impose the additional condition that

$$\|\mathbf{w}(s)\|^2 + \mu(s) = 1, \quad \mathbf{w}(s) \equiv \frac{d}{ds} \mathbf{u}(s), \quad \mu(s) \equiv \frac{d}{ds} \lambda(s), \quad (177)$$

where $s \in \mathbb{R}^1$ is a real-valued parameter and $\lambda(s) \in \mathbb{R}^1$ is a function of s , thereby making s the arc-length parameter along the path $[\mathbf{u}(s), \lambda(s)]$ in the inflated space $\mathbb{R}^{2m+i+k+1}$. As (175) and (176) imply the values of s for which $\lambda(s)$ vanishes determine the zeros of $\mathbf{F}$ (and, consequently, the extrema of R), while the values of s for which $\mu(s)$ vanishes determine the zeros of $\mathbf{F}'$ (and, consequently, the bifurcation, limit, and turning points in the problem under consideration). The Jacobian matrix $\mathbf{F}'(\mathbf{u})$ appearing in (176) has, of course, the same block matrix structure as given in (160).

The numerical solution of (175–177) is computed as follows. Suppose that $(\mathbf{u}_0, \lambda_0)$ is a known solution point of (175). Then, corresponding to this point, there is the pseudo-arc-length parameter point $s_0 \in \mathbb{R}^1$. The starting point is thus set to be $[\mathbf{u}(s_0), \lambda(s_0)] \equiv (\mathbf{u}_0, \lambda_0)$. The direction of the tangent along the solution path at $(\mathbf{u}_0, \lambda_0)$ is given by $[\mathbf{w}(s_0), \mu(s_0)]$, which is obtained by solving (176) and (177) at $s = s_0$. The next point $[\mathbf{u}(s), \lambda(s)]$ on the solution path, for $s \neq s_0$ (but s near s_0), is obtained by solving the following system of equations:

$$\mathbf{G}[\mathbf{u}(s), \lambda(s)] \equiv \mathbf{F}[\mathbf{u}(s)] - \lambda(s) \mathbf{F}[\mathbf{u}(s_0)] = \mathbf{0} \quad (178)$$

and

$$\begin{aligned} \mathbf{M}[\mathbf{u}(s), \lambda(s), s] &\equiv \mathbf{w}(s_0) \bullet [\mathbf{u}(s) - \mathbf{u}(s_0)] \\ &+ \mu(s_0) \bullet [\lambda(s) - \lambda(s_0)] - (s - s_0) = 0. \end{aligned} \quad (179)$$

When $(\mathbf{u}_0, \lambda_0)$ is a regular or a simple limit point of $\mathbf{G}(\mathbf{u}, \lambda)$, the Jacobian

$$J \equiv \begin{bmatrix} \mathbf{F}'(\mathbf{u}) & -\mathbf{F}(\mathbf{u}_0) \\ (\mathbf{w}_0)^T & \mu_0 \end{bmatrix}$$

of (178) and (179) is nonsingular. Furthermore, while the bifurcations in (178) and (179) are identical to those of $\mathbf{F}(\mathbf{u})$, the structure of (178) and (179) at a bifurcation point possesses distinctly advantageous convergence properties over that of $\mathbf{F}(\mathbf{u})$.

To compute $[\mathbf{u}(s), \lambda(s)]$ from (178) and (179), it is advantageous to use Newton's method because of its simplicity and superior convergence properties (quadratic or, at worst, superlinear at bifurcation points). Applying Newton's method to (178) and (179) and rearranging the resulting expressions yield the iterations

$$\Delta \mathbf{u}^v \equiv \mathbf{u}^{v+1} - \mathbf{u}^v, \quad \Delta \lambda^v \equiv \lambda^{v+1} - \lambda^v; \quad (v = 0, 1, \dots), \quad (180)$$

where

$$\Delta \lambda^v = [\mathbf{u}(s_0) \bullet \mathbf{b} - \mathbf{M}(\mathbf{u}^v, \lambda^v, s)] / [\mathbf{w}(s_0) \bullet \mathbf{a} + \mu(s_0)] \quad (181)$$

and

$$\Delta \mathbf{u}^v = (\Delta \lambda^v) \mathbf{a} - \mathbf{b}. \quad (182)$$

In the above equations, the vectors $\mathbf{a}$ and $\mathbf{b}$ denote, respectively, the solutions of

$$\mathbf{F}'(\mathbf{u}^v) \bullet \mathbf{a} = \mathbf{F}(\mathbf{u}_0) \quad (183)$$

and

$$\mathbf{F}'(\mathbf{u}^v) \bullet \mathbf{b} = \mathbf{G}(\mathbf{u}^v, \lambda^v). \quad (184)$$

The initial point $\mathbf{u}_0 = (\boldsymbol{\varphi}_0, \mathbf{y}_0, \boldsymbol{\alpha}_0, \mathbf{z}_0)$ for the Newton iteration is chosen as follows: initially, only the nominal values $\boldsymbol{\alpha}_0$ of the system parameters $\boldsymbol{\alpha}$ are specified, usually as part of the definition of the physical system under consideration. If any of the constraints $\mathbf{g}(\boldsymbol{\alpha})$ are to remain strict equalities over the entire range of variations of the parameters $\boldsymbol{\alpha}$, then we include them in the definition of $N(\boldsymbol{\varphi}, \boldsymbol{\alpha})$, thereby redefining (1) the parameters $\boldsymbol{\alpha}$ that are to be considered as independent variables, and (2) the corresponding structure of the vector $\boldsymbol{\varphi}$ of dependent variables. The corresponding nominal values $\boldsymbol{\varphi}_0$ of the state variables $\boldsymbol{\varphi}$ are then obtained by solving the equation $N(\boldsymbol{\varphi}_0, \boldsymbol{\alpha}_0) = \mathbf{0}$. The nominal values $\mathbf{y}_0$ are obtained as the solutions of the adjoint equations

$$N^+(\boldsymbol{\varphi}_0, \boldsymbol{\alpha}_0, \mathbf{y}) \equiv \nabla_{\boldsymbol{\varphi}} R(\boldsymbol{\varphi}_0, \boldsymbol{\alpha}_0) + [\nabla_{\boldsymbol{\varphi}} N(\boldsymbol{\varphi}_0, \boldsymbol{\alpha}_0)] \mathbf{y}_0 = \mathbf{0}. \quad (185)$$

Furthermore, the inequality constraints $g_j(\boldsymbol{\alpha})$ are arranged to be inactive at $\boldsymbol{\alpha}_0$, so that the inequalities $g_j(\boldsymbol{\alpha}_0) < 0$ are satisfied. This is always possible by appropriately defining the respective functions g_j . Consequently, the initial values for the respective Lagrange multipliers $\mathbf{z}$ are $\mathbf{z}_0 = \mathbf{0}$. Finally, having obtained all the components of $\mathbf{u}_0$ as $\mathbf{u}_0 = (\boldsymbol{\varphi}_0, \mathbf{y}_0, \boldsymbol{\alpha}_0, \mathbf{0})$, we

compute the (first-order) sensitivities at $\mathbf{u}_0 = (\boldsymbol{\varphi}_0, \mathbf{y}_0, \boldsymbol{\alpha}_0, \mathbf{0})$, namely, $\mathbf{S}(\mathbf{u}_0) = \nabla_{\boldsymbol{\alpha}} P(\boldsymbol{\varphi}_0, \boldsymbol{\alpha}_0) + [\nabla_{\boldsymbol{\alpha}} \mathbf{N}(\boldsymbol{\varphi}_0, \boldsymbol{\alpha}_0)] \mathbf{y}_0$. This also completes the calculation for the starting value $\mathbf{F}(\mathbf{u}_0)$, whose components are thus $\mathbf{F}(\mathbf{u}_0) = [\mathbf{0}, \mathbf{0}, \mathbf{S}(\mathbf{u}_0), \mathbf{0}]$.

Having obtained $\mathbf{u}_0$, we select the starting value $\lambda_0 = \lambda(s_0)$ by noting that the point $(\mathbf{u}_0, \lambda_0 = 1)$ satisfies (175); the initial directions $(\mathbf{w}_0, \mu_0)$ are then obtained by solving (176) and (177) at $(\mathbf{u}_0, 1)$. The initial guess for the Newton method is provided by a single Euler step

$$\mathbf{u}^0 = \mathbf{u}_0 + (s - s_0) \mathbf{w}_0, \quad \text{for } v = 0, \quad (186)$$

and

$$\lambda^0 = \lambda_0 + (s - s_0) \mu_0, \quad \text{for } v = 0, \quad (187)$$

where $s - s_0$ can be estimated from convergence theorems for Newton-like methods within a ball of radius $|s - s_0|$ around s_0 .

It is advantageous to use the largest step-length $|s - s_0|$ that still assures convergence of the iterative process. For the illustrative examples to be presented in the next section, the step-length $|s - s_0|$ was estimated from the expression

$$|s - s_0| = \left\{ \|\mathbf{F}(\mathbf{u}_0 + \Delta \mathbf{w}_0) - 2\mathbf{F}(\mathbf{u}_0) + \mathbf{F}(\mathbf{u}_0 - \Delta \mathbf{w}_0)\| \Delta^{-2} \gamma(J) \right\}^{-1/2}, \quad (188)$$

where $\gamma(J)$ is the condition number of the Jacobian J of (178) and (179), and Δ is a small increment. The expression for $|s - s_0|$ given in (188) is obtained by using the Kantorovich method as sufficient condition for the convergence of the Newton method in a ball around s_0 , by neglecting all terms of order higher than two in $|s - s_0|$, and approximating the Hessian $\mathbf{F}''(\mathbf{u}_0)$ by finite differences. While this procedure is useful for many practical applications, it may not always be optimal; therefore, alternative means of obtaining an optimal maximum step length $|s - s_0|$ remain of interest.

Calculating the Newton iterates $\Delta \lambda^v$ and $\Delta \mathbf{u}^v$ from (181) and (182), respectively, requires solving (183) and (184) to obtain the vectors $\mathbf{a}$ and $\mathbf{b}$, respectively. For large-scale problems, $\mathbf{F}'(\mathbf{u})$ is a very large matrix, so a direct solution of (183) and (184) would be impractical. Note, though, that the special structure of $\mathbf{F}'(\mathbf{u})$ was deliberately created by the structural arrangements in the definitions of $\mathbf{F}(\mathbf{u})$ and $\mathbf{u}$ in order to simplify the subsequent task of solving Eqs. (183) and (184), by exploiting the positioning of the zero submatrices and the easy invertibility of the diagonal matrices $\mathbf{Z}_A$ and $\mathbf{C}_I$. By partitioning the vector $\mathbf{a}$ in the form

$$\mathbf{a} = (\mathbf{a}_{\boldsymbol{\varphi}}, \mathbf{a}_{\mathbf{y}}, \mathbf{a}_{\boldsymbol{\alpha}}, \mathbf{a}_A, \mathbf{a}_I), \quad (189)$$

with components having the same dimensions as those of $\boldsymbol{\varphi}, \mathbf{y}, \boldsymbol{\alpha}, A$ (i.e., number of active constraints), and I (i.e., number of inactive constraints), respectively, the task solving (183) is reduced to solving the following matrix equations:

1. When all constraints are inactive, the set A is empty; it then follows from (183) that $\mathbf{a}_A = \mathbf{0}$ and $\mathbf{a}_I = \mathbf{0}$. Hence, (183) is reduced to solving

$$\mathbf{F}_I(\mathbf{u}^v) \begin{pmatrix} \mathbf{a}_{\boldsymbol{\varphi}} \\ \mathbf{a}_{\mathbf{y}} \\ \mathbf{a}_{\boldsymbol{\alpha}} \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{S}(\mathbf{u}_0) \end{pmatrix}, \quad (190)$$

where $F_1(\mathbf{u})$ is the symmetric matrix defined as

$$F_1(\mathbf{u}) \equiv \begin{bmatrix} \nabla_{\varphi} \mathbf{N}^+ & \nabla_{\varphi} \mathbf{N} & \nabla_{\varphi} \mathbf{S} \\ (\nabla_{\varphi} \mathbf{N})^T & \mathbf{0} & (\nabla_{\alpha} \mathbf{N})^T \\ (\nabla_{\varphi} \mathbf{S})^T & \nabla_{\alpha} \mathbf{N} & \nabla_{\alpha} \mathbf{S} \end{bmatrix}. \quad (191)$$

2. When some constraints are active, then $\mathbf{A}$ is not empty but (183) still implies that $\mathbf{a}_l = \mathbf{0}$; in this case, (183) is reduced to solving

$$F_2(\mathbf{u}^v) \begin{pmatrix} \mathbf{a}_{\varphi} \\ \mathbf{a}_y \\ \mathbf{a}_{\alpha} \\ \mathbf{a}_A \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{S}(\mathbf{u}_0) \\ \mathbf{0} \end{pmatrix}, \quad (192)$$

where $F_2(\mathbf{u})$ is the symmetric matrix defined as

$$F_2(\mathbf{u}) = \begin{bmatrix} & & \vdots & \mathbf{0} \\ & F_1(\mathbf{u}) & \vdots & \mathbf{0} \\ \dots & \dots & \vdots & \nabla \mathbf{g}_A \\ \mathbf{0} & \mathbf{0} & (\nabla \mathbf{g}_A)^T & \mathbf{0} \end{bmatrix}. \quad (193)$$

In preparation for solving (184), the vectors $\mathbf{b}$ and $\mathbf{G}$ are partitioned as follows:

$$\mathbf{b} = (\mathbf{b}_{\varphi}, \mathbf{b}_y, \mathbf{b}_{\alpha}, \mathbf{b}_A, \mathbf{b}_l) \quad (194)$$

and

$$\mathbf{G} = (\mathbf{G}_{\varphi}, \mathbf{G}_y, \mathbf{G}_{\alpha}, \mathbf{G}_A, \mathbf{G}_l), \quad (195)$$

respectively. This way, (184) is reduced to solving one or the other of the following matrix equations:

1. When all constraints are inactive, it follows from (184) that

$$\mathbf{b}_A = \mathbf{0}, \quad \mathbf{b}_l = \frac{1}{2} [\mathbf{C}_l(\boldsymbol{\alpha}^v, \mathbf{z}^v)]^{-1} \mathbf{K}(\boldsymbol{\alpha}^v, \mathbf{z}^v). \quad (196)$$

Hence, the remaining components of $\mathbf{b}$ are obtained by solving

$$F_1(\mathbf{u}^v) \begin{pmatrix} \mathbf{b}_{\varphi} \\ \mathbf{b}_y \\ \mathbf{b}_{\alpha} \end{pmatrix} = \begin{pmatrix} \mathbf{G}_{\varphi} \\ \mathbf{G}_y \\ \mathbf{G}_{\alpha} - [\nabla \mathbf{g}(\boldsymbol{\alpha}^v, \mathbf{z}^v)] \mathbf{b}_l \end{pmatrix}. \quad (197)$$

2. When some constraints are active, then $\mathbf{b}_l$ is still given by (196), while solving (184) is reduced to solving the system

$$F_2(\mathbf{u}^v) \begin{pmatrix} \mathbf{b}_{\varphi} \\ \mathbf{b}_y \\ \mathbf{b}_{\alpha} \\ \mathbf{b}_A \end{pmatrix} = \begin{pmatrix} \mathbf{G}_{\varphi} \\ \mathbf{G}_y \\ \mathbf{G}_{\alpha} - [\nabla \mathbf{g}_l(\boldsymbol{\alpha}^v, \mathbf{z}^v)] \mathbf{b}_l \\ \frac{1}{2} [\mathbf{Z}_A(\mathbf{z}^v)]^{-1} \mathbf{K}_A(\boldsymbol{\alpha}^v, \mathbf{z}^v) \end{pmatrix}. \quad (198)$$

The matrix $F'(\mathbf{u})$ and, equivalently, the matrix F_1 (or F_2) become singular at the bifurcation points. It is therefore essential to determine correctly the rank of F_1 or F_2 when solving the equations involving these matrices. In actual computations, singular value decomposition procedures are recommended to determine the null vectors of F_1 (or, respectively, F_2); these null vectors play an essential role for continuing the solution through a bifurcation point.

The Newton algorithm described in the foregoing generates a sequence of points $[\mathbf{u}(s_j), \lambda(s_j)]$ and corresponding tangent directions $[\mathbf{w}(s_j), \mu(s_j)]$, starting at $j = 0$ and continuing until the algorithm terminates at some point j_{final} . When $\lambda(s)$ changes sign between two points, $[\mathbf{u}(s_{r-1}), \lambda(s_{r-1})]$ and $[\mathbf{u}(s_r), \lambda(s_r)]$ on the solution path, then a root $\mathbf{u}^* \equiv \mathbf{u}(s^*)$ of $F(\mathbf{u})$ must correspond to the root $\lambda(s^*) = 0$ that occurs at $s^* \in (s_{r-1}, s_r)$. On the other hand, the points $\mathbf{u}^{**} \equiv \mathbf{u}(s^{**})$ where the determinant of $F'(\mathbf{u})$ vanishes correspond to the points where $\mu(s^{**}) = 0$. These points are found analogously to those where $\lambda(s^*) = 0$, but by monitoring the sign changes in $\mu(s)$ instead of those in $\lambda(s)$. To find the precise locations of the roots $\lambda(s^*) = 0$ and $\mu(s^{**}) = 0$, it is useful to switch, in the respective interval (s_{r-1}, s_r) , from the Newton marching algorithm to the secant method coupled with *regula falsi*, to ensure rapid convergence.

5 Probability Theory and Uncertainty Information

5.1 Assigning Priors under Incomplete Knowledge: Group Theory and Entropy Maximization

Repeated measurements of the same physical quantity yield values that differ from each other, as well as from the true but unknown value of that quantity. This variation in results is due to experimental errors, imperfect instruments, and imperfectly known calibration standards. Hence, around any reported experimental value, there always exists a range of values that may also be plausibly representative of the true value. In turn, this means that all inferences, predictions, engineering computations, and other applications of measured data are necessarily founded on weighted averages over all the possibly true values, with weights indicating the degree of plausibility of each value. These weights and weighted averages are what we call probabilities and expectation values. The interpretation of probabilities as *degrees of plausibility or rational expectation*, on a numerical scale ranging from 0 (impossibility) to 1 (certainty), dates back at least to Bernoulli (1713) and Laplace (1812). Probabilities encode incomplete information, in that persons possessing different information or knowledge would assign different probabilities, and would update the respective probabilities whenever new information became available. Since the true value of physical quantities cannot be measured exactly, nominally measured values are insufficient, by themselves, for applications; the quantitative uncertainties accompanying the measurements are also needed, along with the respective nominal values. Combination of data from different sources involves a weighted propagation (e.g., using sensitivities) of various uncertainties, requiring reasoning from incomplete information for extracting “best” values together with “best” uncertainties from often sparse, incomplete, error-afflicted, and occasionally discrepant experimental data. A wide range of probability-theory concepts and tools are employed in data evaluation and assimilation, from deductive statistics involving mainly frequencies and sample tallies to inductive inference for assimilating non-frequency data and a priori knowledge.

The interpretation of probability as a *relative frequency* is straightforward when studying physical laws, since such laws are assumed to act the same way in repeated experiments, implying that the validity of the assigned probability values can be tested experimentally. However, the concept of probability as a relative frequency becomes questionable when attempting to assign probabilities for very rare (or even uniquely occurring) phenomena such as a core meltdown in a nuclear reactor or the big bang. In such cases, probability must be considered to be a mental construct for expressing a degree of belief about events; this mental construct provides the premises of the Bayesian (or subjective) interpretation of probability. In this interpretation, the underlying sample space is formed of elements that correspond to hypotheses or propositions, that is, statements that are either true or false. Then, the probability associated with a cause or hypothesis A is interpreted as a measure of degree of belief, namely:

$$P(A) \equiv \text{a priori measure of the rational degree of belief} \\ \text{that } A \text{ is the correct cause or hypothesis.}$$

Since a statement like “a measurement will yield a given outcome for a certain fraction of the time” can be regarded as a hypothesis, it follows that the framework of subjective probability includes the interpretation of probability as a relative frequency. In particular, a subjective probability can be associated with the value of an unknown constant; this association reflects one’s confidence that the value of the respective probability is contained within a certain fixed interval.

The elementary conditions for logical consistency imply two fundamental rules, namely, the *sum* and the *product rules*, from which all other mathematical relationships between probabilities can be derived (see, e.g., Cox 1946). These rules can be written in the form

$$P(A|B) + P(\bar{A}|B) = 1; P(A|BC) P(B|C) = P(B|AC) P(A|C), \quad (199)$$

where A , B , and C represent propositions (e.g., “the cross section is larger than 10 barn”). The product AB indicates that “both A and B are true,” $\bar{A}$ indicates “ A is false,” while $P(A|B)$ denotes the probability of A given B . The above notation indicates that all probability assignments are conditional, based on either empirical or theoretical information or on assumptions. The sum rule indicates that, under all circumstances B , the more probable A is the less probable $\bar{A}$, the unit sum of both probabilities representing the certainty that one of these alternatives must be true. The product rule says that, under all circumstances C , the probability that both A and B are true is equal to the probability of A given B , times the probability that, in fact, B is true; note that A and B enter symmetrically in the product rule, so their respective roles are interchangeable. As shown in Cox (1946) and Renyi (1954), the sum and product rules are the only rules that are consistent with the arithmetic of logic (Boolean algebra), under the very general assumptions that $P(\bar{A}|B)$ somehow depends on $P(A|B)$, and that $P(AB|C)$ somehow depends on $P(A|BC)$ and $P(B|C)$, where the P ’s represent degrees of plausibility between 0 and 1.

An immediate consequence of the product rule is *Bayes’ theorem* (Bayes 1763) which, in its simplest form, can be expressed as

$$P(A|BC) = \frac{P(B|AC) P(A|C)}{P(B|C)}. \quad (200)$$

When evaluating scientific data, B usually denotes data that depend on the value of an unknown physical quantity A and on other circumstances C . The (so-called) likelihood function $P(B|AC)$

usually represents a statistical model that indicates how likely the data B would be under the circumstances C , if the unknown quantity were in fact A . Finally, if the “*a priori*” probability, or “*prior*,” for short, $P(A|C)$ is also available, then the “*a posteriori*” probability, or the updated “*posterior*” $P(A|BC)$ is proportional to the product $P(B|AC)P(A|C)$. The prior summarizes what was known about A before the data became available, the likelihood function conveys the impact of the data, and the posterior contains the complete information available for further inference and prediction.

The generalization of (200) to several distinct and mutually exclusive alternatives A_v was obtained in Laplace (1812) in the form

$$P(A_v|BC) = \frac{P(B|A_vC) P(A_v|C)}{\sum_v P(B|A_vC) P(A_v|C)}, \quad v = 1, 2, \dots, N. \quad (201)$$

The above probability is normalized to unity as demanded by the sum rule. For continuous variates A and B , the finite probabilities $P(A|C)$, $P(B|AC)$, etc., are replaced by infinitesimal probabilities $p(A|C)dA$, $P(B|AC)dB$, etc., with probability densities $p(A|C)$, $p(B|AC)$, etc., while the sum over all alternatives is replaced by an integral. Hence, for continuous variates, (201) takes the form

$$p(A|BC) dA = \frac{p(B|AC) p(A|C) dA}{\int p(B|AC) p(A|C) dA}, \quad A_{\min} \leq A \leq A_{\max}. \quad (202)$$

The above forms of Bayes’ theorem provide the cornerstone for data evaluation, assimilation, and calibration (adjustment), indicating how prior knowledge (e.g., a data file) is to be updated with new evidence (new data). The customary way to express Bayes theorem in words is “posterior $\propto$ likelihood $\times$ prior,” where the “prior” distribution summarizes the knowledge extant prior to observing the (new) data, the “likelihood” distribution conveys the impact of the new information brought by the (new) data, while the “posterior” distribution contains the full information available for further inference, prediction, and decision making. Thus, Bayes’ theorem is a formal model for updating, or learning, from observations. Note that the terms “posterior” and “prior” have logical rather than temporal connotations, implying “with” and, respectively, “without” the assimilation of new data. Once a prior probability has been assigned, Bayesian statistics indicates how one’s degree of belief should change after obtaining additional information (e.g., experimental data). Since the prior probability for the data, $P(\text{data})$, does not appear explicitly, the relation

$$\text{“posterior} \propto \text{likelihood} \times \text{prior”}$$

expresses a proportionality rather than an equality.

However, Bayesian statistics provides no fundamental rule for assigning the prior probability to a theory. The choice of the “most appropriate” prior distribution is essential for applying Bayes’ theorem to practical problems, and has caused considerable debates over the years. Thus, when the prior information related to the problem under consideration can be expressed in the form of a probability distribution, this information should certainly be used; in such cases, the repeated application of Bayes’ theorem will serve to refine the knowledge about the respective problem. Ultimately, the proper repeated use of Bayes’ theorem ensures that the impact of the choice of priors on the finally recommended results diminishes as additional information (e.g., measurements) containing consistent data is successively incorporated.

In the absence of any prior information, the principle of insufficient reason works well for coins, dice, playing cards, and other similar cases characterized by discrete alternatives. However, this principle appears to lead to difficulties for continuous alternatives characterized by infinitesimal probabilities, $p(x)dx$, because a continuous uniform distribution, taken to describe equal probabilities, becomes nonuniform under change of variables. For example, when estimating the decay constant λ of a radionuclide, if all decay constants are equally probable a priori, the prior distribution would be $p(\lambda)d\lambda \sim d\lambda$. On the other hand, if all mean lives $\tau = 1/\lambda$ were considered to be equally probable a priori, the prior distribution would be $p(\tau)d\tau \sim d\tau \sim d\lambda/\lambda^2$. In the past, such apparent arbitrariness regarding priors for continuous random quantities had hampered the use of priors and hence the use of Bayes' theorem. However, while establishing *decision theory*, Wald (1950) proved that the optimal strategy for making decisions (i.e., recommending a value for some uncertain quantity, for instance) is based on Bayes' theorem, which renewed the interest in searching logically well-founded prescriptions for assigning priors. A breakthrough in this regard was achieved by Jaynes (1983), who demonstrated that in some very important practical cases, the invariance properties of the problem under investigation uniquely determine the "least informative" prior that describes initial ignorance about numerical values. Thus, if a *location parameter* is to be estimated (e.g., the center μ of a Gaussian), the form of the prior must be invariant under an arbitrary shift of location, for otherwise, some locations would be preferred to others, which would be contrary to the assumption of total ignorance. This invariance implies that $p(\mu)d\mu = p(\mu + c)d(\mu + c)$, which is a functional equation that is satisfied by the uniform distribution, that is,

$$p(\mu) d\mu \sim d\mu, \quad -\infty < \mu < \infty. \quad (203)$$

For a *scale parameter* (e.g., the standard deviation σ of a Gaussian), the form of the prior must be invariant under an arbitrary rescaling, implying that $p(\sigma)d\sigma = p(c\sigma)d(c\sigma)$. The solution of this functional equation is

$$p(\sigma) d\sigma \sim \frac{d\sigma}{\sigma}, \quad 0 < \sigma < \infty. \quad (204)$$

The above prior was introduced for scale parameters by Jeffreys (1939), and is therefore called Jeffreys' prior. Although the least informative priors given in (200) and (201) are not normalizable, they may be considered as limits of very broad, normalizable distributions in the same way as Dirac's delta function may be considered as the limit of normalizable distributions that are extremely broad or extremely narrow, respectively, compared to the distributions with which they are convoluted.

For Bernoulli trials with probability of success θ , the requirement of *invariance under change of evidence* yields the prior

$$p(\theta) d\theta \sim \theta^{-1} (1 - \theta)^{-1} d\theta, \quad 0 \leq \theta \leq 1, \quad (205)$$

if $\theta = 0$ (only failures) and $\theta = 1$ (only successes) cannot be excluded a priori. The posterior probability, obtained with the familiar binomial likelihood function for Bernoulli trials, remains concentrated overwhelmingly on the values $\theta = 1$ (or $\theta = 0$) as long as only successes (or failures) occur. If, on the other hand, exactly one success and one failure was observed, then the posterior is uniform, that is, $p(\theta)d\theta = d\theta$, $0 < \theta < 1$.

In the language of group theory, a least informative prior that describes invariance under a group of continuous transformations is equivalent to the right invariant Haar measure, that is, to the weight function that ensures invariance of integrals over the whole group. More specifically, the right Haar measure is related to the prior by a change of variables, from transformation labels to possible parameters (e.g., the additive group is associated with location parameters, while the multiplicative group is associated with scale parameters).

Although the least informative priors in (203–205) are not normalizable, they may be considered as limits of extremely broad, normalizable distributions, on a linear scale ($d\mu$) or on a logarithmic scale ($d\sigma/\sigma = d(\ln \sigma)$), etc., in the same way as Dirac's delta function may be considered as the limit of extremely narrow, normalizable distributions.

While establishing information theory, Shannon (1948) proved that the lack of information implied by a discrete probability distribution, p_n , with mutually exclusive alternatives can be expressed quantitatively (up to a constant) by its *information entropy*,

$$S = - \sum_{n=1}^N p_n \ln p_n. \quad (206a)$$

Shannon proved that S is the only measure of indeterminacy that satisfies the following three requirements:

1. S is a smooth function of the p_i ;
2. If there are N alternatives, all equally probable, then the indeterminacy, and hence S must grow monotonically as N increases; and
3. Grouping of alternatives leaves S unchanged (i.e., adding the entropy quantifying ignorance about the true group, and the suitably weighted entropies quantifying ignorance about the true member within each group must yield the same overall entropy S as for ungrouped alternatives).

For continuous distributions with probability density, $p(x)$, the expression for its information entropy becomes

$$S = - \int dx p(x) \ln \frac{p(x)}{m(x)}, \quad (206b)$$

where $m(x)$ is a prior density that ensures form invariance under change of variable.

When the underlying distribution $p(x)$ is unknown and needs to be determined from incomplete information, the principle of maximum entropy provides optimal compatibility with the available information, while simultaneously ensuring minimal spurious information content. An important application of the principle of maximal entropy is to the optimal determination of an unknown distribution $p(x)$ when the only available information comprises the (possibly noninformative) prior $m(x)$ and “*integral data*” in the form of moments of several known functions $F_k(x)$ over the unknown distribution $p(x)$, namely,

$$\langle F_k \rangle = \int dx p(x) F_k(x), \quad k = 1, 2, \dots, K. \quad (207)$$

According to the *principle of maximum entropy*, the probability density $p(x)$ would satisfy the “available information” [i.e., would comply with the constraints expressed in (207)] without

implying any spurious information or hidden assumptions, if $p(x)$ maximized the information entropy defined by (206) subject to the known constraints given in (207). This variational problem can be solved by using Lagrange multipliers, λ_k , to obtain the following expression:

$$p(x) = \frac{1}{Z} m(x) \exp \left[- \sum_{k=1}^K \lambda_k F_k(x) \right]. \quad (208)$$

The normalization constant Z in (208) is defined as

$$Z \equiv \int dx m(x) \exp \left[- \sum_{k=1}^K \lambda_k F_k(x) \right]. \quad (209)$$

In statistical mechanics, the normalization constant Z is called the partition function (or sum over states), and carries the entire information available about the possible states of the system. The moments, $\langle F_k \rangle$, representing in practice the “expected integral data,” are obtained by differentiating Z with respect to the respective Lagrange multiplier, that is,

$$\langle F_k \rangle = - \frac{\partial}{\partial \lambda_k} \ln Z, \quad k = 1, 2, \dots, K. \quad (210)$$

In the case of discrete distributions, when the integral data $\langle F_k \rangle$ are not yet known, then $m(x) = 1$, and the maximum entropy algorithm described above yields the uniform distribution, as would be required by the principle of insufficient reason. Therefore, the principle of maximum entropy provides a generalization of the principle of insufficient reason, and can be applied to both discrete and continuous distributions, ranging from problems in which only information about discrete alternatives is available, to problems in which global or macroscopic information is available.

Scientific data is usually reported in the form $\langle x \rangle \pm \Delta x$, with $\Delta x \equiv \sqrt{\text{var } x}$. This information implies the availability of the first and second moments, $\langle x \rangle$ and $\langle x^2 \rangle = \langle x \rangle^2 + (\Delta x)^2$, respectively, of the underlying unknown distribution. In such cases, the maximum entropy algorithm above can be used with $K = 2$, and (208) can be readily used to obtain the form $p(x) \sim \exp(-\lambda_1 x - \lambda_2 x^2)$ as the most objective probability density for further inference. In terms of the known moments $\langle x \rangle$ and $\langle x^2 \rangle$, $p(x)$ would be a Gaussian having the following specific form:

$$p(x|\langle x \rangle, \Delta x) dx = \frac{\exp \left[-\frac{1}{2} \left(\frac{x - \langle x \rangle}{\Delta x} \right)^2 \right]}{[2\pi(\Delta x)^2]^{1/2}} dx, \quad -\infty < x < \infty. \quad (211)$$

When several observables x_i , $i = 1, 2, \dots, n$, are simultaneously measured, the respective results are customarily reported in the form of “best values,” $\langle x_i \rangle$, together with covariance matrix elements $c_{ij} \equiv \langle \varepsilon_i \varepsilon_j \rangle \triangleq \text{cov}(x_j, x_k) = c_{ji}$, $c_{jj} \triangleq \text{var } x_j$, where the errors are defined through the relation $\varepsilon_j \equiv (x_j - \langle x_j \rangle)$. In this case, (208) takes on the form

$$p(\varepsilon|C) d\varepsilon = \frac{1}{Z} \exp \left(- \sum_{i,j} \varepsilon_i \lambda_{ij} \varepsilon_j \right) d\varepsilon = \frac{1}{Z} \exp \left(- \frac{1}{2} \varepsilon^\dagger \Lambda \varepsilon \right) d\varepsilon, \quad (212)$$

where the Lagrange multiplier λ_{ij} corresponds to c_{ij} ; the normalization constant is defined as $Z \equiv \int d\boldsymbol{\varepsilon} \exp(-(1/2)\boldsymbol{\varepsilon}^\dagger \boldsymbol{\Lambda} \boldsymbol{\varepsilon})$; $\boldsymbol{\varepsilon} = (\varepsilon_1, \dots, \varepsilon_n)$ denotes the n -component the vector of errors; $\mathbf{C} \triangleq (c_{ij})_{n \times n}$ is the $n \times n$ covariance matrix for the observables x_i , $i = 1, 2, \dots, n$; and $\boldsymbol{\Lambda} = (\lambda_{ij})_{n \times n}$ denotes the $n \times n$ matrix of Lagrange multipliers. The explicit form of the normalization constant Z in (212) is obtained by performing the respective integrations to obtain

$$Z = \sqrt{\frac{\pi^n}{\det(\boldsymbol{\Lambda})}}. \quad (213)$$

The relationship between the Lagrange multiplier λ_{ij} and the covariance c_{ij} is obtained by differentiating $\ln Z$ with respect to the respective Lagrange multiplier, cf. (210), to obtain

$$c_{ij} = -\frac{\partial}{\partial \lambda_{ij}} \ln Z = \frac{1}{2} (\boldsymbol{\Lambda}^{-1})_{ij} \quad (214)$$

since differentiation of the determinant $\det(\boldsymbol{\Lambda})$ with respect to an element of $\boldsymbol{\Lambda}$ yields the cofactor for this element (which, for a nonsingular matrix, is equal to the corresponding element of the inverse matrix times the determinant). Replacing (213) and (214) in (212) transforms the latter into the form

$$p(\boldsymbol{\varepsilon}|\mathbf{C}) d^n \boldsymbol{\varepsilon} = \frac{\exp\left(-\frac{1}{2}\boldsymbol{\varepsilon}^\dagger \mathbf{C}^{-1} \boldsymbol{\varepsilon}\right)}{\sqrt{\det(2\pi\mathbf{C})}} d^n \boldsymbol{\varepsilon}, \quad -\infty < \varepsilon_i < \infty, \quad (215)$$

with $\langle \boldsymbol{\varepsilon} \rangle = \mathbf{0}$, $\langle \boldsymbol{\varepsilon} \boldsymbol{\varepsilon}^\dagger \rangle = \mathbf{C}$, which is an n -variate Gaussian centered at the origin. In terms of the expected values $\langle x_i \rangle$, the above expression becomes

$$p(\mathbf{x}|\langle \mathbf{x} \rangle, \mathbf{C}) d\mathbf{x} = \frac{\exp\left[-\frac{1}{2}(\mathbf{x} - \langle \mathbf{x} \rangle)^\dagger \mathbf{C}^{-1}(\mathbf{x} - \langle \mathbf{x} \rangle)\right] d\mathbf{x}}{\sqrt{\det(2\pi\mathbf{C})}}, \quad -\infty < x_j < \infty. \quad (216)$$

Thus, the foregoing considerations show that, when only mean values and covariances are known, the maximum entropy algorithm yields the Gaussian probability distribution in (216) as the most objective probability distribution, where $\mathbf{x}$ is the data vector with coordinates x_j ; $\mathbf{C}$ is the covariance matrix with elements C_{jk} ; $d\mathbf{x} \triangleq \prod_j dx_j$ is the volume element in the data space, and the dagger denotes transposition.

Often in practice the variances c_{ii} are known (or can be estimated reasonably well) but the covariances c_{ij} are not, in which case the covariance matrix $\mathbf{C}$ would a priori be diagonal. In such a case, only the Lagrange parameters λ_{ii} would appear in (212), so that the matrix $\boldsymbol{\Lambda}$ would also be a priori diagonal. In other words, in the absence of information about correlations, the maximum entropy algorithm indicates that unknown covariances can be taken to be zero. This is another example of a general property of maximum entropy distributions: all moments vanish unless the constraints demand otherwise. The above results and considerations also provide a justification for the use of the well-known “least squares approximation” method.

Gaussian distributions are often considered appropriate only if many independent random deviations act in concert such that the central limit theorem is applicable. Nevertheless, if only

“best values” and their (co)variances are available, the maximum entropy principle indicates that the corresponding Gaussian is the best choice for all further inferences, regardless of the actual form of the unknown true distribution. Furthermore, in contrast to the central limit theorem, the maximum entropy principle is also valid for correlated data. The maximum entropy principle can also be employed to work with systematic errors when their possible magnitudes can be (at least vaguely) inferred but their signs are not known. The maximum entropy principle indicates that such errors should be described by a Gaussian distribution with zero mean and a width corresponding to the (vaguely) known magnitude, rather than by a rectangular distribution. Although the above results have been derived for observables x_j that vary in the interval for $-\infty < x_j < \infty$, these results can also be used for positive observable x_j ($0 < x_j < \infty$) by considering a logarithmic scale (or lognormal distributions on the original scale). The foregoing considerations underscore the fact that the maximum entropy principle is a powerful tool for the assignment of prior (or any other) probabilities, in the presence of incomplete information.

5.2 Recommending Nominal Values and Uncertainties: Decision Theory

Since probabilities cannot be measured directly, they are either inferred from the results of observations or they are postulated and (partially) verified through accumulated experience. In practice, though, certain random vectors tend to be more probable, so that probability distributions tend to be nonuniform. Therefore, the most important features of probability functions of practical interest are the measures of location and of dispersion, which are provided by the expectation and moments of the respective probability function. If the probability function is known, these moments can be calculated directly, through (a process called) statistical deduction. Otherwise, if the probability function is not known, the respective moments must be estimated from experiments, through (a process called) statistical inference. Since measurements rarely yield true values, it is necessary to introduce surrogate parameters to measure location and dispersion for the observed results. Practice indicates that *location* is best described by the *mean value*, while the *dispersion* of observed results appears to be best described by the *variance*, which is a second-order moment. In particular, the mean value can be interpreted as a locator of the center of gravity, while the variance is analogous to the moment of inertia (which linearly relates applied torque to induced angular acceleration in mechanics). For multivariate probability distributions involving n random variables, all second-order moments are collected in an $n \times n$ matrix called the variance–covariance matrix, or, simply, the covariance matrix.

Ideally, knowledge of scientific and technological data should be described in terms of complete probability distributions. In practice, though, such distributions are seldom available; furthermore, users are often interested only in practical “recommended values” and “error bars.” Prescriptions for recommending rigorously founded “best values” and “error bars” are provided by decision theory, which demonstrates that a disadvantage or penalty arises for any estimate, x_{est} , of an uncertain (unknown) parameter x . This penalty can be described by a *loss function* that vanishes at the unknown true value x but grows as the deviation $|x_{est} - x|$ increases. Near the true value, x , any reasonably smooth loss function can be taken to be proportional to the squared deviation, $(x_{est} - x)^2$, since the Taylor expansion of such a function about zero error

begins with the quadratic term. For a set of given probabilities, P_n , for the various alternatives n , the expected loss function

$$\sum_n P_n (x_{est} - x_n)^2 = \min, \quad (217)$$

is minimized when $x_{est} = \langle x \rangle$; hence $x_{est} = \langle x \rangle$ would be “the recommended value.” For a continuous random quantity with probability density, $p(x)$, the expected loss function is minimized in a similar way, that is,

$$\int dx p(x) (x_{est} - x)^2 = \min, \quad (218)$$

when $x_{est} = \langle x \rangle$. The above considerations indicate that the expected squared error is minimal when $x_{est} = \langle x \rangle$, and is equal, at the minimum, to the variance of the probability distribution. This argument justifies the choice of “mean” and “variance” as the “best indicators” for a distribution under quadratic loss: the “mean” is the optimal estimate of the (always unknown) true value, and the standard deviation (square root of the variance, also called dispersion, standard error, or “ 1σ ” uncertainty) is the best, in the sense of *quadratic loss*, indication of its uncertainty. Hence, parameter estimates should be presented in the form $\langle x \rangle \pm \Delta x$, where $\Delta x = \sqrt{\text{var } x}$. Although other types of loss functions may be preferable for some very specific applications, the quadratic loss is employed as the optimal choice in general, particularly when errors are small and data applications are not specified.

The generalization of the foregoing arguments to several uncertain quantities is accomplished by replacing the scalar observable x with a vector $\mathbf{x}$ whose components are the respective observables. The “*estimate under quadratic loss*” is then described by the vector $\langle \mathbf{x} \rangle$ of mean values, and by the covariance matrix $\langle (\mathbf{x} - \langle \mathbf{x} \rangle) (\mathbf{x} - \langle \mathbf{x} \rangle)^\dagger \rangle$, with the dagger indicating “transposition” (since all components of the respective vectors and matrices are real numbers). Note that the expectation values $\langle \mathbf{x} \rangle$ are averages over the joint distribution of all the coordinates of the vector of observables, and the covariance matrix contains both the respective variances and correlations.

6 Model Calibration Through Data Assimilation for Best-Estimate Predictions

6.1 Introduction

The probabilistic description of possible future computational and experimental outcomes, based on all recognized errors and uncertainties, is the aim of *predictive estimation*. Predictive estimation comprises three key elements: model calibration, model extrapolation, and estimation of the validation domain. *Model calibration* involves the integration (assimilation) of new data for updating (i.e., “calibrating” or “adjusting”) the parameters characterizing a computational model. The procedures for model calibration must encompass the propagation of all relevant uncertainties, including:

1. Data uncertainties (input data, model parameters, initial and boundary conditions, forcing functions, etc);

2. Numerical discretization errors;
3. Discrepancies within the experimental data and/or discrepancies between data and model predictions; and
4. Uncertainties in the physics of the modeled processes (e.g., due to incomplete knowledge).

The results of model validation are best-estimated values for parameters and predicted responses, as well as best-estimate reduced uncertainties (i.e., “smaller” values for the variance–covariance matrices) for the predicted best-estimate parameters and responses, provided all elements involved in the calibration process are consistent with each other. *Quantitative model extrapolation* addresses the prediction of uncertainty in new environments or conditions of interest, including both untested parts of the parameter space and higher levels of system complexity in the validation hierarchy. *Estimation of the validation domain* addresses the estimation of contours of constant uncertainty in the high-dimensional space that characterizes the application of interest.

This section presents a rigorous mathematical methodology for predictive estimation through data assimilation and simultaneous calibration of model parameters and responses for a generic time-dependent physical system, generalizing and setting on a rigorous basis the pioneering work originally presented in Barhen et al. (1980, 1982), as well as the data assimilation methodologies currently used in geophysical sciences [see, e.g., Kalnay 2003; Lewis et al. 2006]. This methodology also provides quantitative indicators, based on uncertainties and sensitivities, for determining the degree of agreement or disagreement relevant to the assimilation and best-estimate adjustment of computational and experimental parameters and responses.

This section is structured as follows: ➤ Sect. 6.2 introduces the mathematical and physical bases for assigning prior probability distributions under incomplete information. ➤ Section 6.3 presents the mathematical framework for data assimilation and simultaneous calibration of model parameters and responses for a generic time-dependent physical system; of course, time-independent systems are included as a particular case within this framework. Furthermore, this framework also encompasses the basic elements for quantitative model extrapolation (i.e., prediction of uncertainty in new environments or conditions of interest, including both untested parts of the parameter space and higher levels of system complexity in the validation hierarchy) and estimation of the validation domain. The data assimilation and best-estimate model calibration methodology presented in ➤ Sect. 6.3 also includes quantitative indicators (based on uncertainties and sensitivities) for data consistency and rejection criteria, in order to determine the degree of agreement (or disagreement) relevant to the assimilation and best-estimate adjustment of parameters and responses, of computations and experiments. The applicability of the methodology presented in ➤ Sect. 6.2 is illustrated in ➤ Sect. 6.4 by performing data assimilation and model calibration for a paradigm transient thermal-hydraulics system of benchmark quality for reactor safety codes.

6.2 Mathematical Formalism

The time-dependent generic physical system to be analyzed in the sequel is considered to comprise N_α^v model parameters and N_r^v distinct responses, respectively, at every time node $v = 1, 2, \dots, N_t$. Hence, at every time node v , the (column) vector α^v of J_α^v system parameters,

and the (column) vector $\mathbf{r}^v$ of J_r^v measured responses can be represented in component form as

$$\boldsymbol{\alpha}^v = \{ \alpha_n^v \mid n = 1, \dots, N_\alpha^v \}, \quad \mathbf{r}^v = \{ r_i^v \mid i = 1, \dots, N_r^v \}, \quad v = 1, \dots, N_t. \quad (219)$$

At any time node v , the system parameters are considered to be variates with mean values $(\boldsymbol{\alpha}^0)^v$. Furthermore, the correlations between two parameters α_i^v and α_j^μ , at two time nodes μ and v , have the general form

$$c_{\alpha,ij}^{v\mu} \equiv \left\langle \left[\alpha_i^v - (\alpha_i^0)^v \right] \left[\alpha_j^\mu - (\alpha_j^0)^\mu \right] \right\rangle. \quad (220)$$

The above covariances constitute the elements of symmetric covariance matrices of the form

$$\mathbf{C}_\alpha^{\mu v} \triangleq \left\langle (\boldsymbol{\alpha} - \boldsymbol{\alpha}^0)^\mu \left[(\boldsymbol{\alpha} - \boldsymbol{\alpha}^0)^v \right]^\dagger \right\rangle = (\mathbf{C}_\alpha^{\mu v})^\dagger = \mathbf{C}_\alpha^{v\mu} = (\mathbf{C}_\alpha^{v\mu})^\dagger. \quad (221)$$

Similarly, the *measured* responses are characterized by mean values $(\mathbf{r}_m)^v$ at a time node v , and by symmetric covariance matrices between two time nodes μ and v defined as

$$\mathbf{C}_m^{\mu v} \triangleq \left\langle (\mathbf{r} - \mathbf{r}_m)^\mu \left[(\mathbf{r} - \mathbf{r}_m)^v \right]^\dagger \right\rangle = (\mathbf{C}_m^{\mu v})^\dagger = \mathbf{C}_m^{v\mu} = (\mathbf{C}_m^{v\mu})^\dagger. \quad (222)$$

In the most general case, the measured responses may be correlated to the parameters through symmetric *response parameter uncertainty* matrices of the form

$$\mathbf{C}_{r\alpha}^{\mu v} \triangleq \left\langle (\mathbf{r} - \mathbf{r}_m)^\mu \left[(\boldsymbol{\alpha} - \boldsymbol{\alpha}^0)^v \right]^\dagger \right\rangle = (\mathbf{C}_{r\alpha}^{\mu v})^\dagger = \mathbf{C}_{r\alpha}^{v\mu} = (\mathbf{C}_{r\alpha}^{v\mu})^\dagger. \quad (223)$$

Note that the matrices $\mathbf{C}_{r\alpha}^{\mu v}$ are *not* bona fide variance–covariance matrices, in that they are not necessarily square positive matrices (often, they are rectangular), and the elements on their respective main diagonals (if they happen to be square) are also covariances (or correlations) rather than variances.

At any given time node v , a response r_i^v can be a function of not only the system parameters at time node v , but also of the system parameters at all previous time nodes μ , $1 \leq \mu \leq v$; this means that $\mathbf{r}^v = \mathbf{R}^v(\mathbf{p}^v)$, where the vector $\mathbf{p}^v \triangleq (\boldsymbol{\alpha}^1, \dots, \boldsymbol{\alpha}^\mu, \dots, \boldsymbol{\alpha}^v)$ has been introduced for notational convenience. In general, the response computed using the model depends nonlinearly and implicitly (in an analytically intractable form) on the model parameters. Furthermore, the uncertainties in parameters and modeling induce uncertainties in the computed responses, and can be computed either by means of statistical methods (for relatively simple models with few parameters) or deterministically, by using the *propagation of moments (errors)* method (see, e.g., Cacuci 2003). In this method, the computed response is linearized via a functional Taylor-series expansion around the nominal values, $\mathbf{p}_0^v \triangleq ((\boldsymbol{\alpha}^0)^1, \dots, (\boldsymbol{\alpha}^0)^\mu, \dots, (\boldsymbol{\alpha}^0)^v)$, of the parameters $\mathbf{p}^v$, as follows:

$$\mathbf{r}^v = \mathbf{R}^v(\mathbf{p}^v) = \mathbf{R}^v(\mathbf{p}_0^v) + \sum_{\mu=1}^v \mathbf{S}^{v\mu}(\mathbf{p}_0^\mu) \left[\boldsymbol{\alpha}^\mu - (\boldsymbol{\alpha}^0)^\mu \right] + \dots, \quad v = 1, \dots, N_t, \quad (224)$$

where $\mathbf{R}^v(\mathbf{p}_0^v)$ denotes the vector of computed responses at a time node v , at the nominal parameter values $\mathbf{p}_0^v$, while $\mathbf{S}^{v\mu}(\mathbf{p}_0^\mu)$, $1 \leq \mu \leq v$, represents the $(J_r \times J_\alpha)$ -dimensional matrix containing the first Gateaux-derivatives of the computed responses with respect to the parameters, defined as

$$\mathbf{S}^{v\mu}(\mathbf{p}_0^\mu) \triangleq \begin{pmatrix} s_{11}^{v\mu} & \cdots & s_{1N}^{v\mu} \\ \vdots & s_{in}^{v\mu} & \vdots \\ s_{l1}^{v\mu} & \cdots & s_{lN}^{v\mu} \end{pmatrix} \triangleq \begin{pmatrix} \frac{\partial R_1^v(\mathbf{p}_0^\mu)}{\partial \alpha_1^\mu} & \cdots & \frac{\partial R_1^v(\mathbf{p}_0^\mu)}{\partial \alpha_N^\mu} \\ \vdots & \frac{\partial R_l^v(\mathbf{p}_0^\mu)}{\partial \alpha_n^\mu} & \vdots \\ \frac{\partial R_l^v(\mathbf{p}_0^\mu)}{\partial \alpha_1^\mu} & \cdots & \frac{\partial R_l^v(\mathbf{p}_0^\mu)}{\partial \alpha_N^\mu} \end{pmatrix}, \quad 1 \leq \mu \leq v. \quad (225)$$

Since the response $\mathbf{R}^v(\mathbf{p}_0^v)$ at time node v can depend only on parameters $(\alpha^0)^\mu$ which appear up to the current time node v , it follows that $\mathbf{S}^{v\mu} = \mathbf{0}$ when $\mu > v$, and hence nonzero terms in the expansion shown in (224) can only occur in the range $1 \leq \mu \leq v$. It is important to note that discretization parameters are also included among the components of α , and the sensitivities of responses to such discretization parameters can be computed as described in Cacuci (2003) and Cacuci et al. (2005).

By introducing the block matrix

$$\mathbf{S} \triangleq \begin{pmatrix} \mathbf{S}^{11} & \cdots & \mathbf{0} \\ \vdots & \ddots & \vdots \\ \mathbf{S}^{N_t,1} & \cdots & \mathbf{S}^{N_t,N_t} \end{pmatrix}, \quad (226)$$

and the (block) column vectors

$$\begin{aligned} \alpha &\triangleq (\alpha^1, \dots, \alpha^\mu, \dots, \alpha^{N_t}), \quad \mathbf{r} \triangleq (\mathbf{r}^1, \dots, \mathbf{r}^\mu, \dots, \mathbf{r}^{N_t}), \\ \mathbf{R}(\alpha^0) &\triangleq (\mathbf{R}^1, \dots, \mathbf{R}^\mu, \dots, \mathbf{R}^{N_t}), \end{aligned} \quad (227)$$

the system shown in (224) can be written in the form

$$\mathbf{r} = \mathbf{R}(\alpha^0) + \mathbf{S}(\alpha - \alpha^0) + \text{higher order terms} \quad (228)$$

Applying the propagation of errors method (see, e.g., Cacuci 2003), which involves the formal integration of (228) over the unknown joint distribution of the parameters α , yields the following expressions for the expectation value, $\langle \mathbf{r} \rangle$, of the response $\mathbf{r}$, and the corresponding covariance matrix, $C_{rc}(\alpha^0)$, of the computed responses: that is,

$$\langle \mathbf{r} \rangle = \mathbf{R}(\alpha^0), \quad (229)$$

and

$$C_{rc}(\alpha^0) \triangleq \langle \delta \mathbf{r} \delta \mathbf{r}^\dagger \rangle = [\mathbf{S}(\alpha^0)] \langle \delta \alpha \delta \alpha^\dagger \rangle [\mathbf{S}(\alpha^0)]^\dagger = [\mathbf{S}(\alpha^0)] C_\alpha [\mathbf{S}(\alpha^0)]^\dagger. \quad (230)$$

The covariance matrix of the computed responses, C_{rc} , has the symmetric structure

$$C_{rc} \triangleq \begin{pmatrix} C_{rc}^{11} & \cdots & C_{rc}^{1N_t} \\ \vdots & \ddots & \vdots \\ C_{rc}^{N_t 1} & \cdots & C_{rc}^{N_t N_t} \end{pmatrix}, \text{ with components defined as}$$

$$C_{rc}^{\nu\mu} = \sum_{\eta=1}^{\nu} \sum_{\rho=1}^{\mu} S^{\nu\eta} C_{\alpha}^{\eta\rho} (S^{\mu\rho})^{\dagger} = (C_{rc}^{\mu\nu})^{\dagger}; \quad \nu, \mu = 1, \dots, N_t. \quad (231)$$

As indicated by (229), the expectation value of the computed responses for linearized models in which the numerical errors are neglected is given by the value of the response computed at the nominal parameter values.

Applying now the maximum entropy algorithm described in ► Sect. 5.1 [cf. (216)] to the computational and experimental information described in (219–231) indicates that the most objective probability distribution for this information is a multivariate Gaussian of the form

$$p(z|C) d(z) = \frac{\exp[-(1/2) Q(z)]}{\det(2\pi C)^{1/2}} d(z), \quad Q(z) \equiv z^{\dagger} C^{-1} z, \quad -\infty < z_j < \infty, \quad (232)$$

where

$$z \equiv \begin{pmatrix} \alpha - \alpha^0 \\ r - r_m \end{pmatrix}, \quad \alpha^0 \triangleq ((\alpha^0)^1, \dots, (\alpha^0)^{\mu}, \dots, (\alpha^0)^{N_t}), \quad (233)$$

$$C \equiv \begin{pmatrix} C_{\alpha} & C_{\alpha r} \\ C_{r\alpha} & C_m \end{pmatrix}, \quad (234)$$

with

$$C_{\alpha} = \begin{pmatrix} C_{\alpha}^{11} & C_{\alpha}^{12} & \cdots & \cdots \\ C_{\alpha}^{21} & C_{\alpha}^{22} & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & C_{\alpha}^{N_t N_t} \end{pmatrix}, \quad C_{\alpha r} = \begin{pmatrix} C_{\alpha r}^{11} & C_{\alpha r}^{12} & \cdots & \cdots \\ C_{\alpha r}^{21} & C_{\alpha r}^{22} & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & C_{\alpha r}^{N_t N_t} \end{pmatrix}, \quad \text{and}$$

$$C_m = \begin{pmatrix} C_m^{11} & C_m^{12} & \cdots & \cdots \\ C_m^{21} & C_m^{22} & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & C_m^{N_t N_t} \end{pmatrix}$$

The posterior information, which is contained in (232) and (228), can now be condensed into a recommended best-estimate value $(z^{be})^{\nu}$ at a time node ν for the parameters α^{ν} and responses r^{ν} , together with corresponding best-estimate recommended uncertainties for these quantities. If a loss function is given, decision theory indicates how these best-estimate quantities are to be computed. If no specific loss function is provided, the recommended best-estimate updated posterior mean vector $(z^{be})^{\nu}$ and its respective best-estimate posterior covariance matrix are usually evaluated by assuming “quadratic loss.” In such a case, the bulk of the contribution to the distribution $p(z|C)$ in (232) is extracted by computing it at the point in phase space where the respective exponent attains its minimum, subject to (228). Subsequent computations are facilitated by recasting (228) in the form

$$Z(\alpha^0) z + d = 0, \quad d \triangleq R(\alpha^0) - r_m, \quad (235)$$

where $\mathbf{r}_m \triangleq (\mathbf{r}_m^1, \dots, \mathbf{r}_m^\mu, \dots, \mathbf{r}_m^{N_t})$ is the vector comprising all of the experimentally measured responses, $\mathbf{d} \triangleq \mathbf{R}(\boldsymbol{\alpha}^0) - \mathbf{r}_m$ is a vector of “deviations” reflecting the discrepancies between the nominal computations and the nominally measured responses, while $\mathbf{Z}$ denotes the partitioned matrix

$$\mathbf{Z} \triangleq \begin{pmatrix} \mathbf{S} & \mathbf{U} \end{pmatrix}; \quad \mathbf{U} \triangleq \begin{pmatrix} -\mathbf{I}^{11} & \dots & \mathbf{0} \\ \vdots & \ddots & \vdots \\ \mathbf{0} & \dots & -\mathbf{I}^{N_t N_t} \end{pmatrix}, \quad (236)$$

where $\mathbf{I}^{\nu\nu}$, $\nu = 1, \dots, N_t$, denotes the identity matrix of the corresponding dimensions.

Computing the stationary point of $Q(\mathbf{z})$ subject to (235) poses a constrained minimization problem which can be solved by introducing Lagrange multipliers, $\boldsymbol{\lambda}$, to construct the augmented Lagrangian functional $P(\mathbf{z}, \boldsymbol{\lambda})$ defined as

$$P(\mathbf{z}, \boldsymbol{\lambda}) \equiv Q(\mathbf{z}) + 2\boldsymbol{\lambda}^\dagger [\mathbf{Z}(\boldsymbol{\alpha}^0)\mathbf{z} + \mathbf{d}] = \min, \quad \text{at } \mathbf{z} = \mathbf{z}^{be} \equiv \begin{pmatrix} \boldsymbol{\alpha}^{be} - \boldsymbol{\alpha}^0 \\ \mathbf{r}^{be} - \mathbf{r}_m \end{pmatrix}. \quad (237)$$

where $\boldsymbol{\lambda} = (\lambda^1, \dots, \lambda^\nu, \dots, \lambda^{N_t})$ denotes the corresponding vector of the Lagrange multipliers. In the above expression, the superscript “be” denotes “best-estimated values,” and the factor “2” was introduced for convenience in front of $\boldsymbol{\lambda}$ in order to simplify the subsequent algebraic derivations. The point $\mathbf{z}^{be}$ where the functional $P(\mathbf{z}, \boldsymbol{\lambda})$ attains its extremum (minimum) is defined implicitly through the conditions

$$\nabla_{\mathbf{z}} P(\mathbf{z}, \boldsymbol{\lambda}) = \mathbf{0}, \quad \nabla_{\boldsymbol{\lambda}} P(\mathbf{z}, \boldsymbol{\lambda}) = \mathbf{0}, \quad \text{at } \mathbf{z} = \mathbf{z}^{be}. \quad (238)$$

The solution to the above constrained minimization problem is detailed in Cacuci and Ionescu-Bujor (2010). The final results (Cacuci and Ionescu-Bujor 2010) for the predictive best-estimate parameters— responses, and their corresponding reduced uncertainties (covariance matrices) are as follows:

1. The best-estimate predicted nominal values for the calibrated (adjusted) parameters:

$$\boldsymbol{\alpha}^{be} = \boldsymbol{\alpha}^0 + \left(\mathbf{C}_{\alpha r} - \mathbf{C}_\alpha [\mathbf{S}(\boldsymbol{\alpha}^0)]^\dagger \right) [\mathbf{C}_d(\boldsymbol{\alpha}^0)]^{-1} \mathbf{d}. \quad (239)$$

In component form, the above expression for the calibrated best-estimate parameter values becomes

$$(\boldsymbol{\alpha}^{be})^\nu = (\boldsymbol{\alpha}^0)^\nu + \sum_{\mu=1}^{N_t} \left\{ \left[\mathbf{C}_{\alpha r}^{\nu\mu} - \sum_{\rho=1}^{\mu} \mathbf{C}_\alpha^{\nu\rho} (\mathbf{S}^\dagger)^{\mu\rho} \right] \left[\sum_{\eta=1}^{N_t} \mathbf{K}_d^{\mu\eta} \mathbf{d}^\eta \right] \right\}, \quad \nu = 1, \dots, N_t, \quad (240)$$

where $\mathbf{K}_d^{\nu\eta}$ denotes the corresponding (ν, η) -element of the block-matrix $\mathbf{C}_d^{-1}$, with the block-matrix $\mathbf{C}_d(\boldsymbol{\alpha}^0)$ defined as follows:

$$\begin{aligned} \mathbf{C}_d(\boldsymbol{\alpha}^0) &\triangleq \langle \mathbf{d} \mathbf{d}^\dagger \rangle = \left\langle \left(\delta \mathbf{r} - \mathbf{S}(\boldsymbol{\alpha}^0) \delta \boldsymbol{\alpha} \right) \left(\delta \mathbf{r}^\dagger - \delta \boldsymbol{\alpha}^\dagger [\mathbf{S}(\boldsymbol{\alpha}^0)]^\dagger \right) \right\rangle \\ &= \mathbf{C}_{rc}(\boldsymbol{\alpha}^0) - \mathbf{C}_{r\alpha} [\mathbf{S}(\boldsymbol{\alpha}^0)]^\dagger - [\mathbf{S}(\boldsymbol{\alpha}^0)] \mathbf{C}_{\alpha r} + \mathbf{C}_m \end{aligned} \quad (241)$$

In component form, the matrix C_d is expressed as

$$C_d \triangleq \begin{pmatrix} C_d^{11} & \cdots & C_d^{1N_t} \\ \vdots & \ddots & \vdots \\ C_d^{N_t 1} & \cdots & C_d^{N_t N_t} \end{pmatrix} = \begin{pmatrix} C_{rc}^{11} + C_m^{11} & \cdots & C_{rc}^{1N_t} + C_m^{1N_t} \\ \vdots & \ddots & \vdots \\ C_{rc}^{N_t 1} + C_m^{N_t 1} & \cdots & C_{rc}^{N_t N_t} + C_m^{N_t N_t} \end{pmatrix} \\ - \begin{pmatrix} C_{r\alpha}^{11} (S^\dagger)^{11} + S^{11} C_{\alpha r}^{11} & \cdots & S^{11} C_{\alpha r}^{1N_t} + \sum_{\rho=1}^{N_t} C_{r\alpha}^{1\rho} (S^\dagger)^{N_t \rho} \\ \vdots & \ddots & \vdots \\ C_{r\alpha}^{N_t 1} (S^\dagger)^{11} + \sum_{\rho=1}^{N_t} S^{N_t \rho} C_{\alpha r}^{\rho 1} & \cdots & \sum_{\rho=1}^{N_t} [C_{r\alpha}^{N_t \rho} (S^\dagger)^{N_t \rho} + S^{N_t \rho} C_{\alpha r}^{\rho N_t}] \end{pmatrix}. \quad (242)$$

2. The best-estimate predicted nominal values for the calibrated (adjusted) responses:

$$r(\alpha^{be}) = r_m + \left(C_m - C_{r\alpha} [S(\alpha^0)]^\dagger \right) [C_d(\alpha^0)]^{-1} d. \quad (243)$$

At a specific time node v , each component $(r^{be})^v$ of $r(\alpha^{be})$ has the explicit form

$$(r^{be})^v = (r_m)^v + \sum_{\mu=1}^{N_t} \left\{ \left[C_m^{v\mu} - \sum_{\rho=1}^{\mu} C_{r\alpha}^{v\rho} (S^\dagger)^{\mu\rho} \right] \left[\sum_{\eta=1}^{N_t} K_d^{\mu\eta} d^\eta \right] \right\}, \quad v = 1, \dots, N_t. \quad (244)$$

3. The expressions for the best-estimate predicted covariances C_α^{be} and C_r^{be} , corresponding to the best-estimate parameters α^{be} and responses $r(\alpha^{be})$, together with the predicted best-estimate parameter–response covariance matrix $C_{\alpha r}^{be}$ are as follows:

$$C_\alpha^{be} \triangleq \left\langle (\alpha - \alpha^{be})(\alpha - \alpha^{be})^\dagger \right\rangle = C_\alpha - [C_{\alpha d}(\alpha^0)][C_d(\alpha^0)]^{-1}[C_{\alpha d}(\alpha^0)]^\dagger, \quad (245)$$

$$C_r^{be} \triangleq \left\langle (r - r(\alpha^{be}))(r - r(\alpha^{be}))^\dagger \right\rangle = C_m - [C_{rd}(\alpha^0)][C_d(\alpha^0)]^{-1}[C_{rd}(\alpha^0)]^\dagger, \quad (246)$$

$$C_{r\alpha}^{be} = C_{\alpha r}^{be} \triangleq \left\langle (\alpha - \alpha^{be})(r - r(\alpha^{be}))^\dagger \right\rangle = C_{r\alpha} - [C_{rd}(\alpha^0)][C_d(\alpha^0)]^{-1}[C_{\alpha d}(\alpha^0)]^\dagger, \quad (247)$$

where

$$C_{rd}(\alpha^0) \triangleq \left\langle (r - r_m) d^\dagger \right\rangle = \left(C_m - C_{r\alpha} [S(\alpha^0)]^\dagger \right), \quad (248)$$

$$C_{\alpha d}(\alpha^0) \triangleq \left\langle (\alpha - \alpha^0) d^\dagger \right\rangle = \left(C_{\alpha r} - C_\alpha [S(\alpha^0)]^\dagger \right), \quad (249)$$

For completeness, the block-matrix components, which correlate two (distinct or not) time nodes of the above calibrated best-estimate covariance matrices are given below:

$$\left(C_{\alpha}^{be}\right)^{\nu\mu} = C_{\alpha}^{\nu\mu} - \sum_{\eta=1}^{N_t} \sum_{\rho=1}^{N_t} \left[C_{\alpha r}^{\nu\rho} - \sum_{\pi=1}^{\rho} C_{\alpha}^{\nu\pi} \left(s^{\dagger}\right)^{\rho\pi} \right] K_d^{\rho\eta} \left[C_{r\alpha}^{\eta\mu} - \sum_{\pi=1}^{\eta} S^{\eta\pi} C_{\alpha}^{\pi\mu} \right], \quad (250)$$

$$\left(C_r^{be}\right)^{\nu\mu} = C_m^{\nu\mu} - \sum_{\eta=1}^{N_t} \sum_{\rho=1}^{N_t} \left[C_m^{\nu\rho} - \sum_{\pi=1}^{\rho} C_{r\alpha}^{\nu\pi} \left(s^{\dagger}\right)^{\rho\pi} \right] K_d^{\rho\eta} \left[C_m^{\eta\mu} - \sum_{\pi=1}^{\eta} S^{\eta\pi} C_{\alpha}^{\pi\mu} \right], \quad (251)$$

$$\left(C_{r\alpha}^{be}\right)^{\nu\mu} = C_{r\alpha}^{\nu\mu} - \sum_{\eta=1}^{N_t} \sum_{\rho=1}^{N_t} \left[C_m^{\nu\rho} - \sum_{\pi=1}^{\rho} C_{r\alpha}^{\nu\pi} \left(s^{\dagger}\right)^{\rho\pi} \right] K_d^{\rho\eta} \left[C_{\alpha r}^{\eta\mu} - \sum_{\pi=1}^{\eta} S^{\eta\pi} C_{\alpha}^{\pi\mu} \right], \quad (252)$$

Note in (245) that a symmetric positive matrix is subtracted from the initial parameter covariance matrix C_{α} ; hence, in this sense, *the best-estimate predicted parameter uncertainty matrix C_{α}^{be} has been reduced by the calibration (adjustment) procedure, through the introduction of new information from experiments*. Similarly, a symmetric positive matrix is subtracted in (246) from the initial covariance matrix C_m of the experimental responses; hence, *the best-estimate predicted response covariance matrix C_r^{be} has been improved (reduced) through the introduction of new experimental information*. Furthermore, Eq. (247) indicates that the calibration (adjustment) procedure will introduce correlations between the calibrated (adjusted) parameters and responses even if the parameters and response were initially uncorrelated, since $C_{r\alpha}^{be} \neq 0$ even if $C_{r\alpha} = 0$, that is,

$$C_{r\alpha}^{be} = C_m \left[C_{rc}(\alpha^0) + C_m \right]^{-1} \left[S(\alpha^0) \right] C_{\alpha}, \quad \text{when } C_{r\alpha} = 0. \quad (253)$$

As the above expression indicates, the adjustment (calibration) modifies the correlations among the parameters through couplings introduced by the sensitivities of the participating responses. In the calibration procedure, the sensitivities play the role of weighting functions for propagating the initial parameter covariances and experimental-response covariances to the adjusted best-estimate predicted quantities. Thus, as indicated by (245–247), the incorporation of additional (experimental) information in the adjustment (calibration) process reduces the variances of the adjusted parameters and responses while also modifying their correlations.

Note that, Eq. (246) expresses the best-estimate response covariance matrix, C_r^{be} in terms of the initial covariance matrix, C_m , of the experimental responses. Alternatively, it is of interest to derive the expression of the computed best-estimate response covariance matrix, C_{rc}^{be} , directly from the model (the subscript “rc,” denotes “computed response,” to distinguish it from the covariance C_r^{be} , which is obtained directly from the calibration/adjustment process). The starting point for computing C_{rc}^{be} is the linearization of the model, similar to that shown in (228), but around α^{be} , instead of α^0 , that is,

$$r = R(\alpha^{be}) + S(\alpha^{be})(\alpha - \alpha^{be}) + \text{higher order terms.} \quad (254)$$

It follows from (254) that

$$\begin{aligned}
 \mathbf{C}_{rc}^{be} &= \left\langle \left(\mathbf{r} - \mathbf{R}(\boldsymbol{\alpha}^{be}) \right) \left(\mathbf{r} - \mathbf{R}(\boldsymbol{\alpha}^{be}) \right)^\dagger \right\rangle \triangleq \left[\mathbf{S}(\boldsymbol{\alpha}^{be}) \right] \left\langle \left(\boldsymbol{\alpha} - \boldsymbol{\alpha}^{be} \right) \left(\boldsymbol{\alpha} - \boldsymbol{\alpha}^{be} \right)^\dagger \right\rangle \left[\mathbf{S}(\boldsymbol{\alpha}^{be}) \right]^\dagger \\
 &= \left[\mathbf{S}(\boldsymbol{\alpha}^{be}) \right] \mathbf{C}_\alpha^{be} \left[\mathbf{S}(\boldsymbol{\alpha}^{be}) \right]^\dagger \\
 &= \left[\mathbf{S}(\boldsymbol{\alpha}^{be}) \right] \left[\mathbf{C}_\alpha - \left(\mathbf{C}_{\alpha r} - \mathbf{C}_\alpha \left[\mathbf{S}(\boldsymbol{\alpha}^0) \right]^\dagger \right) \left[\mathbf{C}_d(\boldsymbol{\alpha}^0) \right]^{-1} \left(\mathbf{C}_{\alpha r} - \left[\mathbf{S}(\boldsymbol{\alpha}^0) \right] \mathbf{C}_\alpha \right) \right] \left[\mathbf{S}(\boldsymbol{\alpha}^{be}) \right]^\dagger
 \end{aligned} \tag{255}$$

Comparing (255) to (246) reveals that, in general, $\mathbf{C}_{rc}^{be} \neq \mathbf{C}_r^{be}$ since $\mathbf{S}(\boldsymbol{\alpha}^{be}) \neq \mathbf{S}(\boldsymbol{\alpha}^0)$. Nevertheless, when the model is “perfect” (i.e., free of higher-order numerical errors) and exactly linear, then the sensitivity matrix $\mathbf{S}$ is independent of the parameter values $\boldsymbol{\alpha}$, that is,

$$\mathbf{S}(\boldsymbol{\alpha}^{be}) = \mathbf{S}(\boldsymbol{\alpha}^0) = \mathbf{S}, \quad \text{for “perfect” and linear models,} \tag{256}$$

Using (256) in (255) reduces the later expression to

$$\begin{aligned}
 \mathbf{C}_{rc}^{be} &= \mathbf{S} \left[\mathbf{C}_\alpha - \left(\mathbf{C}_{\alpha r} - \mathbf{C}_\alpha \mathbf{S}^\dagger \right) \mathbf{C}_d^{-1} \left(\mathbf{C}_{\alpha r} - \mathbf{S} \mathbf{C}_\alpha \right) \right] \mathbf{S}^\dagger \\
 &= \mathbf{C}_{rc} - \left(\mathbf{C}_{rc} - \mathbf{S} \mathbf{C}_{\alpha r} \right) \left[\mathbf{C}_{rc} + \mathbf{C}_e - \mathbf{C}_{r\alpha} \mathbf{S}^\dagger - \mathbf{S} \mathbf{C}_{\alpha r} \right]^{-1} \left(\mathbf{C}_{rc} - \mathbf{C}_{\alpha r} \mathbf{S}^\dagger \right) \\
 &= \mathbf{C}_r^{be}, \quad \text{for “perfect” linear models.}
 \end{aligned} \tag{257}$$

It is important to note that the computation of the best-estimate parameter and response values, together with their corresponding best-estimate uncertainties, cf., (239), (243), and (245–247) require the inversion of a single matrix, namely, the matrix $\mathbf{C}_d(\boldsymbol{\alpha}^0)$ defined in (242). This is usually advantageous in practice, since the order of the matrix $\mathbf{C}_d(\boldsymbol{\alpha}^0)$ is given by the number of measured (or computed) responses, which are most often considerably smaller than the number of model parameters under consideration.

On the other hand, when the number of parameter exceeds the number of responses, it is possible to derive alternative expressions for the best-estimate calibrated parameters and their corresponding best-estimate covariances, by performing all derivations in the “parameter space” rather than in “response space.” This entails using (228) to eliminate the response (variables) $\mathbf{r}$ at the outset, and carrying out the minimization procedure solely for the parameters (variables), $\boldsymbol{\alpha}$. Equivalently, as shown in (Cacuci et al. 2010), the Sherman–Morrison–Woodbury extension can be employed to obtain the alternative expression

$$\begin{aligned}
 \mathbf{C}_d^{-1} &\triangleq \left(\mathbf{C}_{rc} - \mathbf{C}_{r\alpha} \mathbf{S}^\dagger - \mathbf{S} \mathbf{C}_{\alpha r} + \mathbf{C}_m \right)^{-1} \\
 &= \mathbf{A}^{-1} - \mathbf{A}^{-1} \mathbf{S} \left(\mathbf{C}_\alpha^{-1} + \mathbf{S}^\dagger \mathbf{A}^{-1} \mathbf{S} \right)^{-1} \mathbf{S}^\dagger \mathbf{A}^{-1}; \quad \mathbf{A} \triangleq \mathbf{C}_m - \mathbf{C}_{r\alpha} \mathbf{S}^\dagger - \mathbf{S} \mathbf{C}_{\alpha r}.
 \end{aligned} \tag{258}$$

The above expression provides the bridge between the “response-space” and “parameter-space” formulations. This expression also highlights the fact that the response-space formulation

requires a single inversion of a square symmetric matrix (namely, the matrix, C_d) of the same dimensions as the number of responses. In contradistinction, the “parameter space” formulation requires the inversion of three symmetric matrices, two of which have dimensions equal to the number of parameters and one of dimensions equal to the number of responses. Hence, from a computational standpoint, the “response-space” formulations should be used whenever possible.

As highlighted by the expression of C_d in (242), it is essential to note that the inverse matrix, C_d^{-1} , incorporates simultaneously all of the available information about the system parameters and responses, at all time nodes [i.e., $v = 1, 2, \dots, N_t$]. Specifically, at any time node, v , C_d^{-1} incorporates information not only from time nodes prior in time to v (i.e., information regarding the “past” and “present” states of the system) but also from time nodes posterior in time to v (i.e., information about the “future” states of the system). Through the matrix C_d^{-1} , at any specified time node v , the calibrated best-estimates parameters $(\mathbf{a}^{be})^v$ and responses $\mathbf{r}(\mathbf{a}^{be}) \triangleq \mathbf{r}^{be}$, together with the corresponding calibrated best-estimate covariance matrices $(C_\alpha^{be})^{v\mu}$, $(C_r^{be})^{v\mu}$, and $(C_{ar}^{be})^{v\mu}$ will also incorporate automatically all of the available information about the system parameters and responses at all time nodes [i.e., $v = 1, 2, \dots, N_t$].

In this respect, the methodology presented in this section is conceptually related to the “foresight” aspects encountered in decision analysis. It is also important to note that, in practice, the application of the methodology developed in this section involves two distinct computational stages. A complete sensitivity data base (i.e., sensitivities $s_{ni}^{v\mu}$ at all times nodes, $v, \mu = 1, \dots, N_t$) needs to be generated “off-line” prior to performing the “data assimilation” and “model calibration” (or data adjustment) stages. All sensitivities are subsequently combined with appropriate covariance matrices to compute calibrated best-estimate responses, parameters, and best-estimate covariance matrices.

Because of the “foresight” and “off-line” characteristics, the methodology presented in this section can be called the “off-line with foresight” data assimilation and adjustment (model calibration) methodology, underscoring that all sensitivities are generated separately, prior to performing the uncertainty analysis, and that foresight characteristics are included in the calibration procedure. Since the incorporation of foresight effects involves the inversion of the matrix, C_d , this methodology is best suited for problems involving relatively few time nodes. For large-scale highly nonlinear problems involving many time nodes, the matrix C_d becomes very large, requiring large amounts of computer storage; the inversion of C_d may become prohibitively expensive in such cases. These difficulties can be reduced at the expense of using less than the complete information available at any specific time node. For example, even in time-dependent problems in which the entire time history is known (e.g., transient behavior of reactor systems), one may nevertheless choose to use only information up to the current time index, and disregard the information about “future” system states.

On the other hand, in dynamical problems such as climate or weather prediction, in which the time variable advances continuously and states beyond the current time are not known, information about future states cannot be reliably accounted for anyway. Thus, the most common way of reducing the dimensionality of the data assimilation and model calibration problem is to disregard information about future states and limit the amount of information assimilated about “past states.” Data assimilation and model calibration procedure using such a limited amount of information can be performed either off-line or on-line, assimilating the new data as the time index advances.

The simplest case of dynamic data assimilation and model calibration is when these operations are performed by using information on-line from only two successive time steps. In this particular case, the expressions given by (240), (244), and (250–252) for the best-estimate predicted calibrated quantities reduce (see Cacuci et al. (2010) for details) to the following explicit formulas:

1. The components $(\alpha^{be})^k$, representing the calibrated best-estimates for the system parameters at time node, k , can be written in a particular form of (240), as follows:

$$(\alpha^{be})^k = (\alpha^0)^k + \sum_{\mu=k-1}^k \left\{ \left[\mathbf{C}_{\alpha r}^{k\mu} - \sum_{\rho=k-1}^{\mu} \mathbf{C}_{\alpha}^{k\rho} (\mathbf{s}^\dagger)^{\mu\rho} \right] \left[\sum_{\eta=k-1}^k \mathbf{K}_d^{\mu\eta} \mathbf{d}^\eta \right] \right\}, \quad k = 1, 2, \dots, N_t. \quad (259)$$

2. The vector $(\mathbf{r}^{be})^k$, representing the best-estimates predicted values for the system parameters at a time node, k , take on the following particular form of (244):

$$(\mathbf{r}^{be})^k = (\mathbf{r}_m)^k + \sum_{\mu=k-1}^k \left\{ \left[\mathbf{C}_m^{k\mu} - \sum_{\rho=k-1}^{\mu} \mathbf{C}_{r\alpha}^{k\rho} (\mathbf{s}^\dagger)^{\mu\rho} \right] \left[\sum_{\eta=k-1}^k \mathbf{K}_d^{\mu\eta} \mathbf{d}^\eta \right] \right\}, \quad k = 1, 2, \dots, N_t. \quad (260)$$

3. The components $(\mathbf{C}_\alpha^{be})^{\nu\mu}$, $(\nu, \mu = k-1, k)$, of the calibrated best-estimate covariance matrix, $\mathbf{C}_\alpha^{be}$, for the calibrated best-estimates system parameters is obtained by particularizing (250) to two consecutive time nodes $(k-1, k)$, $k = 1, 2, \dots, N_t$, leading to

$$(\mathbf{C}_\alpha^{be})^{\nu\mu} = \mathbf{C}_\alpha^{\nu\mu} - \sum_{\eta=k-1}^k \sum_{\rho=k-1}^k \left[\mathbf{C}_{\alpha r}^{\nu\rho} - \sum_{\pi=k-1}^{\rho} \mathbf{C}_\alpha^{\nu\pi} (\mathbf{s}^\dagger)^{\rho\pi} \right] \mathbf{K}_d^{\rho\eta} \left[\mathbf{C}_{r\alpha}^{\eta\mu} - \sum_{\pi=k-1}^{\eta} \mathbf{s}^{\eta\pi} \mathbf{C}_\alpha^{\pi\mu} \right],$$

for $\nu = k-1, k; \quad \text{and} \quad \mu = k-1, k; \quad k = 1, 2, \dots, N_t.$ (261)

4. The components $(\mathbf{C}_r^{be})^{\nu\mu}$, $(\nu, \mu = k-1, k)$, of the calibrated best-estimate covariance matrix $\mathbf{C}_r^{be}$, for the best-estimate responses takes on the following particular form of (251):

$$(\mathbf{C}_r^{be})^{\nu\mu} = \mathbf{C}_m^{\nu\mu} - \sum_{\eta=k-1}^k \sum_{\rho=k-1}^k \left[\mathbf{C}_m^{\nu\rho} - \sum_{\pi=k-1}^{\rho} \mathbf{C}_{r\alpha}^{\nu\pi} (\mathbf{s}^\dagger)^{\rho\pi} \right] \mathbf{K}_d^{\rho\eta} \left[\mathbf{C}_m^{\eta\mu} - \sum_{\pi=k-1}^{\eta} \mathbf{s}^{\eta\pi} \mathbf{C}_{\alpha r}^{\pi\mu} \right],$$

for $\nu = k-1, k; \quad \text{and} \quad \mu = k-1, k; \quad k = 1, 2, \dots, N_t.$ (262)

5. The components $(\mathbf{C}_{\alpha r}^{be})^{\nu\mu}$, $(\nu, \mu = k-1, k)$, of the best-estimate response-parameter covariance matrix $\mathbf{C}_{\alpha r}^{be}$ take on the following particular form of (252):

$$(\mathbf{C}_{\alpha r}^{be})^{\nu\mu} = \mathbf{C}_{r\alpha}^{\nu\mu} - \sum_{\eta=k-1}^k \sum_{\rho=k-1}^k \left[\mathbf{C}_m^{\nu\rho} - \sum_{\pi=k-1}^{\rho} \mathbf{C}_{r\alpha}^{\nu\pi} (\mathbf{s}^\dagger)^{\rho\pi} \right] \mathbf{K}_d^{\rho\eta} \left[\mathbf{C}_{r\alpha}^{\eta\mu} - \sum_{\pi=k-1}^{\eta} \mathbf{s}^{\eta\pi} \mathbf{C}_\alpha^{\pi\mu} \right]$$

for $\nu = k-1, k; \quad \text{and} \quad \mu = k-1, k; \quad k = 1, 2, \dots, N_t.$ (263)

For each time node, $k = 1, 2, \dots, N_t$, the quantities $\mathbf{K}_d^{v\eta}$ which appear in (259–263) have the following expressions:

$$\mathbf{K}_d^{k-1,k-1} = \left[\mathbf{C}_d^{k-1,k-1} - \mathbf{C}_d^{k-1,k} \left(\mathbf{C}_d^{k,k} \right)^{-1} \mathbf{C}_d^{k,k-1} \right]^{-1} \quad (264)$$

$$= \left(\mathbf{C}_d^{k-1,k-1} \right)^{-1} + \left(\mathbf{C}_d^{k-1,k} \right)^{-1} \mathbf{C}_d^{k-1,k} \mathbf{K}_d^{k,k} \mathbf{C}_d^{k,k-1} \left(\mathbf{C}_d^{k-1,k-1} \right)^{-1}$$

$$\mathbf{K}_d^{k-1,k} = - \left(\mathbf{C}_d^{k-1,k-1} \right)^{-1} \mathbf{C}_d^{k-1,k} \left[\mathbf{C}_d^{k,k} - \mathbf{C}_d^{k,k-1} \left(\mathbf{C}_d^{k-1,k-1} \right)^{-1} \mathbf{C}_d^{k-1,k} \right]^{-1} \quad (265)$$

$$= - \left(\mathbf{C}_d^{k-1,k-1} \right)^{-1} \mathbf{C}_d^{k-1,k} \mathbf{K}_d^{k,k}$$

$$\mathbf{K}_d^{k,k} = \left[\mathbf{C}_d^{k,k} - \mathbf{C}_d^{k,k-1} \left(\mathbf{C}_d^{k-1,k-1} \right)^{-1} \mathbf{C}_d^{k-1,k} \right]^{-1} \quad (266)$$

$$= \left(\mathbf{C}_d^{k,k} \right)^{-1} + \left(\mathbf{C}_d^{k,k} \right)^{-1} \mathbf{C}_d^{k,k-1} \mathbf{K}_d^{k-1,k-1} \mathbf{C}_d^{k-1,k} \left(\mathbf{C}_d^{k,k} \right)^{-1}$$

$$\mathbf{K}_d^{k,k-1} = - \left(\mathbf{C}_d^{k,k} \right)^{-1} \mathbf{C}_d^{k,k-1} \left[\mathbf{C}_d^{k-1,k-1} - \mathbf{C}_d^{k-1,k} \left(\mathbf{C}_d^{k,k} \right)^{-1} \mathbf{C}_d^{k,k-1} \right]^{-1} \quad (267)$$

$$= - \left(\mathbf{C}_d^{k,k} \right)^{-1} \mathbf{C}_d^{k,k-1} \mathbf{K}_d^{k-1,k-1}$$

For *time-independent* problems, the (time-dependent) results derived in (259–263) reduce to expressions that are formally identical to (239), (243), and (245–247). Hence, the later expressions can be used directly to obtain the best-estimate predicted values for parameters, responses, and their respective covariances. Recall that modeling errors can be treated in a manner similar to parameter uncertainties, by including the discretization intervals among the components of the vector α of model parameters, as detailed in Cacuci (2003) and Cacuci et al. (2005).

Finally, it is important to emphasize that the explicit formulas presented in this section are based on the linearized relationship between responses and parameters that customarily underlies the “propagation of moments” method, that is, (228), without considering nonlinearities explicitly. Nevertheless, this limitation is not as severe as it may appear at first glance, since nonlinear relations between computed responses and model parameters can be treated by considering (228) iteratively, starting with the known nominal values of the quantities involved. The first iteration (in such an iterative procedure) would yield all of the major explicit results derived in (239), (243), and (245–247). The subsequent iteration would be the results of (239), (243), and (245–247) as the “prior information” in a second application of these formulas, and compute the new (“second iteration”) best-estimate quantities by using once again these formulas. This iterative procedure would be continued until the best-estimated values would converge within a small, user-specified convergence criterion.

6.3 Data Consistency and Rejection Criteria

The actual application of the model calibration (adjustment) algorithms, cf. (239), (243), and (245–247), to a physical system is straightforward in principle, although it can become computationally very demanding in terms of data handling and computational speed requirements. It is also important to note that the indiscriminate incorporation of all (seemingly relevant)

experimental-response data could produce a set of calibrated (adjusted) parameter values that might differ unreasonably much from the corresponding original nominal values. Worse yet, the indiscriminate use of information might even fail to improve the agreement between the calculated and measured values of some of the very responses by which the library was calibrated (adjusted).

When calibrating (adjusting) a library of model parameters, it is tacitly assumed that the given parameters are basically “correct,” except that they are not sufficiently accurate for the objective at hand. The calibration procedure uses additional data (e.g., experimental responses) for improving the parameter values while reducing their uncertainties. Although such additional information induces modifications of the original parameter values, the adjusted parameters are still generally expected to remain consistent with their original nominal values, within the range of their original uncertainties. As just mentioned, however, indiscriminate calibration of model parameters by experimental responses that significantly deviate from their respective computed values would significantly modify the resulting adjusted parameters.

On the other hand, calibrating a parameter library by using measured responses that are very close to their respective computed values would cause minimal parameter modifications and a nearly perfect reproduction of the given responses by the adjusted library (as would be expected). In such a case, the given responses would be considered as being consistent with the parameter library, in contradistinction to adjustment by inconsistent experimental information, in which case the adjustment could fail because of inconsistencies. These considerations clearly underscore the need for using a quantitative indicator to measure the mutual and joint consistency of the information available for model calibration.

As shown in Cacuci et al. (2010), the minimum value, $Q_{\min} \equiv Q(\mathbf{z}^{be})$, of $Q(\mathbf{z})$ takes on the following expression:

$$Q_{\min} \equiv Q(\mathbf{z}^{be}) = \mathbf{d}^\dagger [\mathbf{C}_d(\boldsymbol{\alpha}^0)]^{-1} \mathbf{d}, \quad \mathbf{d} \triangleq \mathbf{R}(\boldsymbol{\alpha}^0) - \mathbf{r}_x. \quad (268)$$

As the above expression indicates, $Q_{\min} \equiv Q(\mathbf{z}^{be})$ represents the square of the length of the vector $\mathbf{d}$, measuring (in the corresponding metric) the deviations between the experimental and nominally computed responses. Note that $Q_{\min} \equiv Q(\mathbf{z}^{be})$ can be evaluated directly from the given data (i.e., given parameters and responses, together with their original uncertainties) after having inverted the deviation-vector uncertainty matrix $\mathbf{C}_d(\boldsymbol{\alpha}^0)$. It is also very important to note that $Q_{\min} \equiv Q(\mathbf{z}^{be})$ is independent of calibrating (or adjusting) the original data. As the dimension of $\mathbf{d}$ indicates, the number of degrees of freedom characteristic of the calibration under consideration is equal to the number of experimental responses. In the extreme case of absence of experimental responses, no actual calibration takes place, since $\mathbf{d} = \mathbf{R}(\boldsymbol{\alpha}^0)$, so that the best-estimate parameter values are just the original nominal values, that is, $(\boldsymbol{\alpha}^{be})^k = (\boldsymbol{\alpha}^0)^k$; an actual adjustment occurs only when at least one experimental response is included.

Replacing (268) in (232) shows that the bulk of the contribution to the joint posterior probability distribution, which comes from the point $\mathbf{z} = \mathbf{z}^{be}$, takes on the form of the following multivariate Gaussian distribution:

$$p(\mathbf{z}^{be} | \mathbf{C}) \sim \exp \left[-\frac{1}{2} Q(\mathbf{z}^{be}) \right] = \exp \left\{ -\frac{1}{2} [\mathbf{r}_x - \mathbf{R}(\boldsymbol{\alpha}^0)]^\dagger [\mathbf{C}_d(\boldsymbol{\alpha}^0)]^{-1} [\mathbf{r}_x - \mathbf{R}(\boldsymbol{\alpha}^0)] \right\}. \quad (269)$$

The above relation indicates that experimental responses can be considered as random variables approximately described by a multivariate Gaussian distribution with means located at the nominal values of the computed responses, and with a covariance matrix $\mathbf{C}_d(\boldsymbol{\alpha}^0)$. In turn, the random variable, $Q_{\min} \equiv Q(\mathbf{z}^{be})$, obeys a χ^2 -distribution with n degrees of freedom, where n denotes the total number of experimental responses considered in the calibration (adjustment) procedure. Since $Q_{\min} \equiv Q(\mathbf{z}^{be})$ is the “ χ^2 of the calibration (adjustment) at hand,” it can be used as an indicator of the agreement between the computed and experimental responses, measuring essentially the consistency of the experimental responses with the model parameters. Recall that the χ^2 (chi-square) distribution with n degrees of freedom of the continuous variable x , $0 \leq x < \infty$, is defined as

$$P(x < \chi^2 < x + dx) \triangleq k_n(x) dx \\ = \frac{1}{2^{n/2} \Gamma(n/2)} x^{n/2-1} e^{-x/2} dx, \quad x > 0, (n = 1, 2, \dots). \quad (270)$$

The χ^2 -distribution is a measure of the deviation of a “true distribution” (in this case: the distribution of experimental responses) from the hypothetic one (in this case: a Gaussian). The mean and variance of x are $\langle x \rangle = n$ and $\text{var}(x) = 2n$. Further, practically useful asymptotic properties of the χ^2 -distribution for $n \rightarrow \infty$ are as follows: (1) x is asymptotically normal with mean n and variance $2n$; (2) x/n is asymptotically normal with mean 1 and variance $2/n$; (3) $\sqrt{2x}$ is asymptotically normal with mean $\sqrt{2n-1}$ and variance 1. Although the χ^2 -distribution is extensively tabulated, the notation is not uniform in the literature for the various derived quantities (in particular, for the corresponding cumulative distribution functions and fractiles). The cumulative distributions, denoted here by $P_n(\chi^2)$ and $Q_n(\chi^2)$, are defined as

$$P_n(\chi_0^2) \triangleq P(\chi^2 \leq \chi_0^2) \triangleq \int_0^{\chi_0^2} k_n(t) dt; \quad Q_n(\chi_0^2) \\ \triangleq P(\chi^2 \geq \chi_0^2) \triangleq \int_{\chi_0^2}^{\infty} k_n(t) dt = 1 - P_n(\chi_0^2) \quad (271)$$

In practice, one rejects a hypothesis using the χ^2 -distribution when, for a given significance level α and number of degrees of freedom n , the value of $Q_{\min} \equiv \chi^2$ exceeds a chosen critical fractile value $\chi_{\alpha}^2(n)$. Published tables often show $\chi_{1-\alpha}^2(n)$ versus α . When the number of degrees of freedom is large ($n > 30$), a useful asymptotic approximation is $\chi_{\alpha}^2(n) \approx (1/2)(\sqrt{2n-1} + z_{2\alpha})^2$, with $z_{2\alpha}$ denoting the corresponding fractile of the standard normal distribution $\Phi_0(z)$, computed by solving the equation $2\Phi_0(z_{2\alpha}) = 1 - 2\alpha$, using the tabulated tables for $\Phi_0(z)$. For large or small values of α , a more accurate approximation is $\chi_{\alpha}^2(n) \approx n(1 - (2/9m) + z_{2\alpha}\sqrt{(2/9m)})^3$. It may be often more convenient to transform χ^2 to the variate $t = \chi^2/n$ (i.e., “ χ^2 per degree of freedom”), in which case the transformed distribution, $g_n(t)$, becomes $g_n(t) = nk_n(nt)$, with mean value $\langle t \rangle = 1$ and variance $2/n$.

For *model calibration* (adjustment), it is important to assess if: (1) *the response and data measurements are free of gross errors* (blunders such as wrong settings, mistaken readings, etc.), and (2) *the measurements are consistent with the assumptions regarding the respective means, variances, and covariances*. For example if $\chi^2/n \approx 1$, then the measurements are very likely to be both, free of gross errors and consistent with the assumptions. However, if $\chi^2/n \gg 1$ or $\chi^2/n \ll 1$, the measurements (or at least some measurements), the assumptions, or both are

suspect. In particular, unusually large values $\chi^2/n \gg 1$ could be obtained when the original variances are underestimated; increasing them beyond their assumed nominal values would cause the adjusted values of χ^2/n and $P_n(\chi^2)$ to decrease accordingly. The reverse argument would apply if the *a priori* values of χ^2/n and $P_n(\chi^2)$ were unusually small (e.g., $\chi^2/n \ll 1$, $P_n(\chi^2) \sim 10^{-4}$), which could be the result of *a priori* overestimated variances. A practical quantitative criterion for the “acceptance” or “rejection” of experimental results in conjunction with a given “theoretical” model (i.e., in conjunction with the assumptions regarding the variates underlying the model) is to accept the value of χ^2/n whenever $0.15 < P_n(\chi^2) < 0.85$, in analogy to the “ 1σ ” range of normal distributions. Note that, when setting an acceptance criterion for χ^2/n of the general form

$$\alpha < P_n(\chi^2) < 1 - \alpha \quad (272)$$

the exact value of α is not essential and is subject to personal judgment. This is because the probability $P_n(\chi^2)$ is still sensitive to the value of χ^2/n due to the fact that $\chi^2/n \simeq 1 \pm \sqrt{(2/n)}$ (except for few degrees of freedom, e.g., for $n \leq 5$), so the acceptable range of χ^2/n narrows as $1/\sqrt{n}$ (see also the previously noted asymptotic forms for χ^2_α/n). In other words, moderate changes in χ^2/n lead to significant relative changes in $P_n(\chi^2)$. For example, the central 50%-range of $\chi^2/20$ is (0.77, 1.19), and the corresponding 90%-range is (0.54, 1.57), implying that values of $\chi^2/20$ below $\simeq 0.4$ or above $\simeq 2.0$ would be definitely unacceptable.

In addition to measuring the overall consistency of a given set of parameters and responses, the quantity χ^2/n also measures the consistency among the measured responses. Hence, an entire data set (model parameters and/or experimental responses) should not be indiscriminately disqualified because of a “too high” or “too low” value of χ^2/n , since even a single “outlying” response could significantly degrade the set’s overall consistency. Note that a simple-minded assessment and ranking of “questionable responses” according to the values of the “individual consistencies” (i.e., the values of χ^2 obtained for each response as if it were the only response available for calibrating the entire set of parameters), would be very likely misleading. This is because the sum of the respective “individual consistencies” [which would numerically be obtained by dividing the squares of the deviations, d_i^2 , through the sum of the respective variances of the computed and measured responses $\text{var}(r_i^{\text{comp}}) + \text{var}(r_i^{\text{exp}})$], would not be equal to the “joint consistency” (i.e., the joint χ^2) of the entire set of experimental responses. This is because the deviation-vector uncertainty matrix $\mathbf{C}_d(\boldsymbol{\alpha}^0) \triangleq \mathbf{C}_{rc}(\boldsymbol{\alpha}^0) - \mathbf{C}_{r\alpha}[\mathbf{S}(\boldsymbol{\alpha}^0)]^\dagger - [\mathbf{S}(\boldsymbol{\alpha}^0)]\mathbf{C}_{\alpha r} + \mathbf{C}_x$ is generally non-diagonal, even if both $\mathbf{C}_{rc}(\boldsymbol{\alpha}^0)$ and $\mathbf{C}_x$ are diagonal. On the other hand, verifying the consistency of all partial sets of the array of n responses with respect to their consistency with the given library is usually impractical, since the number of partial sets of an array of n responses is $2^n - 1$; hence, such a verification would be practically feasible only when the number of measured responses is very small.

A procedure that has been successfully used to identify successively the responses which are least consistent with a given library of parameters is based on leaving out one response at a time and evaluating $\chi^2_{n-1}(1)$ for the remaining $n - 1$ responses. The response left out is subsequently returned to the response set, another response (response “two”) is eliminated, and the corresponding $\chi^2_{n-1}(2)$ is evaluated. This procedure is continued until all remaining $\chi^2_{n-1}(i)$, $i = 3, \dots, n$, are successively evaluated. The response that yields the lowest χ^2_{n-1} when eliminated is considered to be “the least consistent,” and is thus ranked “last” in the consistency sequence, and eliminated from further consideration. The evaluation procedure is then repeated

for the remaining $n - 1$ (“more consistent”) responses, to identify the “second least consistent response,” which is then ranked next-to-last. The procedure is then repeatedly applied to the successive, fewer and fewer partial response sets until establishing the complete consistency sequence. Establishing such a consistency sequence requires only $n(n + 1)/2$ computations of χ^2 , as compared to $(2^n - 1)$ calculations needed to assign χ^2 values to all possible partial sets of n responses.

The quantity χ^2/n measures the consistency of any set of n experimentally measured responses with a given library of model parameters, in the sense that if χ_1^2 refers to a specific set of n experimental responses and χ_2^2 to another set of n responses, then $\chi_1^2 < \chi_2^2$ means that the first set is more consistent with the library than the second. On the other hand, when varying the number of responses, it is not *a priori* obvious whether the set yielding a smaller χ^2/n is also necessarily the most consistent with the given parameters. As an example, consider the value $P_n(\chi^2) = 0.85$, which can correspond to both $\chi^2/5 = 1.623$ and also to $\chi^2/10 = 1.453$. If, for example, one set of five responses would give a computed value $\chi^2/5 = 1.6$, and second set of ten responses would give $\chi^2/10 = 1.5$, the first set would be considered to be the “more consistent set,” for it falls within the “central 70% range,” whereas the second set does not. In such situations, it is preferable to use the quantity $Q_n(\chi^2) = 1 - P_n(\chi^2)$, as an additional measure of consistency.

Quite generally, therefore, the calibration (adjustment) of a set of model parameters and experimental responses must include the verification of their mutual consistency, which is performed by first generating the consistency sequence, and then determining the probabilities $Q_i(\chi^2)$, when $i = 1, 2, \dots, n$, while generating the sequence. The less consistent responses will show up at the end of the sequence, and the probabilities $Q_i(\chi^2)$ will generally decrease as i approaches the total number of responses, n . Such an analysis would identify the significantly less-consistent responses, and would also indicate the level of consistency of all response subsets along the consistency sequence.

In parallel, the irregular model parameters, if any, must also be identified. This can be done by computing not only χ^2 for any response subset, but also computing from (239) the corresponding best-estimate parameters $\alpha^{be} = \alpha^0 + (C_{\alpha r} - C_{\alpha} [S(\alpha^0)]^\dagger) [C_d(\alpha^0)]^{-1} d$. This way, the actual individual parameter adjustments induced by the respective response subset are also examined while proceeding step-by-step along the consistency sequence, noting which parameters vary more than others, and by how much. Usually, the parameter adjustments induced by the more consistent subsets of responses tend to be marginal. The less consistent responses and the questionable parameters would tend to undergo larger adjustments, requiring specific further examinations.

6.4 Illustrative Application to Model Calibration for a Benchmark Blowdown Experiment

The best-estimate model calibration methodology presented in the foregoing sections will be applied in this section to perform a predictive best-estimate analysis of benchmark blowdown experiment IC1 (Haque et al. 1992a, b; Petrucci 2008), which was performed at London’s Imperial College. This benchmark experiment involves the rapid depressurization (blowdown) of a

vertical cylindrical vessel with flat ends, containing nitrogen. The geometry of the vessel and the system diagram are depicted in  Fig. 7, below.

The geometry of the vessel is characterized by the vessel's internal diameter D , height H , wall thickness S , volume V , and surface area A_s . Since the vessel's wall is thin, the internal and external wall surface areas of the vessel can both be considered to be equal to A_s . Furthermore, the heat transfer coefficients (between nitrogen and the internal wall, and between air and the external wall) through the horizontal surfaces of the flat ends of the vessel are computed using the same correlations as for the heat transfer coefficients through the vertical cylindrical surface. The vessel wall is made of stainless steel, with thermal conductivity K_w and thermal diffusivity λ_w . The gas outside the vessel is air at stagnant conditions, characterized by the pressure P_{env} and temperature T_{env} .

Initially, the vessel contains M_0 kilograms of pressurized nitrogen gas at temperature T_0 and pressure P_0 , and the vessel wall is at the uniform temperature $\theta(x, t) = T_0$. The transient depressurization process is initiated at $t = t_0$ by releasing the gas through a valve with a discharge flow rate, F_{out} . The nitrogen gas is considered to behave as a perfect gas that is characterized by the heat capacity at constant pressure, C_p , and the specific gas constant, R . These fundamental properties yield the following derived properties for some specified pressure, P , and temperature, T : the heat capacity at constant volume, $C_v = C_p - R$; the ratio between the heat capacities at constant pressure and volume, $k = C_p/C_v$; the gas specific volume, $v = RT/P$; the gas enthalpy, $h = C_p T$; the gas internal energy, $u = C_v T$.

Denoting the temperature within the vessel's wall by $\theta(x, t)$, the gas pressure in the vessel by $P(t)$, and the gas temperature by $T(t)$, the equations describing the corresponding energy and mass balances, subject to a rigid volume constraint and gas-state relations, can be conveniently represented in operator form as follows (Petruzzi et al. 2010):

$$N[u(t), \alpha] = \mathbf{0}, \quad t > 0, \quad (273)$$

Figure 7
Transient thermal-hydraulics (blowdown) system diagram

subject to the initial conditions

$$\begin{cases} P(t=0) = P_0, \\ T(t=0) = T_0, \\ \theta_j(t=0) = \theta_{j,0} = T_0 = T_{env}, \quad j = 0, \dots, J. \end{cases} \quad (274)$$

where $\alpha \triangleq (\alpha_i)$, $i = 1, \dots, I \triangleq 281 + 2 + 1 = 284$, denotes the vector of system parameters (including the two initial conditions, P_0 and T_0 , as well as the discretization parameter Δx), with the following components, in order:

$$\alpha = \left\{ D, H, S, A, C_d, T_{env}, P_{env}, a, b, c, d, k, R, \lambda_w, K_w, g, \rho_{N,P_r,T_s}, Cp_{N,P_r,T_s}, \dots \right. \quad (275)$$

$$\left. \dots, k_{N,P_r,T_s}, \mu_{N,P_r,T_s}, \beta_{N,P_r,T_s}, \rho_{A,T_k}, Cp_{A,T_k}, k_{A,T_k}, \mu_{A,T_k}, \beta_{A,T_k}, P_0, T_0, \Delta x \right\} \quad (276)$$

denotes the column vector of $J + 3$ state variables, where $\theta_j(t) \triangleq \theta(x_j, t)$; and $\Delta x \triangleq S/J$; $x_j \triangleq j \cdot \Delta x$; for $j = 1, \dots, J - 1$;

$N[u(t), \alpha]$ denotes the following $J + 3$ -component column vector:

$$N[u(t), \alpha] \triangleq \begin{Bmatrix} \frac{dP}{dt} - N_1 \\ \frac{dT}{dt} - N_2 \\ N_3 \\ \vdots \\ \frac{\partial \theta_j(t)}{\partial t} - N_{3+j} \\ \vdots \\ N_{J+3} \end{Bmatrix} \quad (277)$$

where

$$N_1 \triangleq \frac{1}{V} \cdot \{ (k-1) \cdot [h_N(T, \theta_0, P; \alpha) \cdot (\theta_0(t) - T(t)) \cdot A_S] - F_{out}(P, T, \alpha) \cdot k \cdot R \cdot T(t) \};$$

$$N_2 \triangleq \frac{k-1}{V} \cdot \left[\frac{[h_N(T, \theta_0, P; \alpha) \cdot (\theta_0(t) - T(t)) \cdot A_S] \cdot T(t)}{P(t)} - F_{out}(P, T, \alpha) \cdot \frac{R \cdot T(t)^2}{P(t)} \right];$$

$$N_3 \triangleq -K_w \cdot \frac{\theta_1(t) - \theta_0(t)}{\Delta x} + h_N(T, \theta_0, P; \alpha) \cdot (\theta_0(t) - T(t));$$

$$N_{3+j} \triangleq \lambda_w \cdot \frac{\theta_{j+1}(t) - 2 \cdot \theta_j(t) + \theta_{j-1}(t)}{(\Delta x)^2}; \quad j = 1, \dots, J-1;$$

$$N_{3+J} \triangleq K_w \cdot \frac{\theta_J(t) - \theta_{J-1}(t)}{\Delta x} + h_A(\theta_J; \alpha) \cdot (\theta_J(t) - T_{env}).$$

The time dependence in (273) is discretized using the forward Euler method for the equations containing the time derivatives of P and T , and using the backward Euler method for the remaining equations. This discretization yields the following system of nonlinear algebraic equations:

$$A(X^n) X^{n+1} = B(X^n) \quad (278)$$

where $\mathbf{X}^{n+1}$ denotes the vector of unknown state variables at the new time step $(n+1)$, $\mathbf{B}$ denotes a vector of quantities known from the previous time step n , while $\mathbf{A}$ denotes a sparse matrix of coefficients. The explicit form of these quantities is given below:

$$\mathbf{X}^{n+1} = \begin{pmatrix} P^{n+1} \\ T^{n+1} \\ \theta_0^{n+1} \\ \vdots \\ \theta_j^{n+1} \\ \vdots \\ \theta_J^{n+1} \end{pmatrix}; \quad \mathbf{B} = \begin{pmatrix} P^n + \Delta t \cdot \left\{ \frac{1}{V} \cdot [(k-1) \cdot (h_N^n \cdot (\theta_0^n - T^n) \cdot A_S) - F_{out}^n \cdot k \cdot R \cdot T^n] \right\} \\ T^n + \Delta t \cdot \left\{ \frac{k-1}{V} \cdot \left[\frac{(h_N^n \cdot (\theta_0^n - T^n) \cdot A_S) \cdot T^n}{P^n} - F_{out}^n \cdot \frac{R \cdot (T^n)^2}{P^n} \right] \right\} \\ \theta_0^n \\ \vdots \\ \theta_j^n \\ \vdots \\ \theta_J^n + 2 \cdot F_o \cdot h_A^n \cdot \frac{\Delta x}{K_w} \cdot T_{env} \end{pmatrix}$$

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & \dots & 0 \\ 0 & 1 & 0 & 0 & 0 & \dots & 0 \\ 0 & -2F_o h_N^n \frac{\Delta x}{K_w} & 1 + 2F_o \left(1 + h_N^n \frac{\Delta x}{K_w} \right) & -2F_o & 0 & \dots & 0 \\ 0 & 0 & 0 & 0 & \vdots & \dots & \vdots \\ \vdots & \vdots & \vdots & 1 + 2F_o & -F_o & 0 & \vdots \\ 0 & 0 & \vdots & -F_o & 1 + 2F_o & -F_o & \vdots \\ \vdots & \vdots & \vdots & 0 & -F_o & 1 + 2F_o & \vdots \\ \vdots & \vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & \dots & 0 & -2F_o & 1 + 2F_o \left(1 + h_A^n \frac{\Delta x}{K_w} \right) \end{pmatrix}$$

where: $F_o \triangleq \lambda_w \cdot \Delta t / \Delta x^2$; $x_j \triangleq j \cdot \Delta x$; $t^n \triangleq n \cdot \Delta t$; $\theta_j^n \triangleq \theta(x_j, t^n)$; $P^n \triangleq P(t^n)$; $T^n \triangleq T(t^n)$. Note also that:

1. $F_{out}^n \triangleq F_{out}(P^n, T^n; \alpha) = F_{break}^n$, with

$$F_{break}^n = \begin{cases} F_{choke}^n = C_d \cdot A \cdot \sqrt{k \cdot \frac{(P^n)^2}{R \cdot T^n} \cdot \left(\frac{2}{k+1} \right)^{\frac{k+1}{k-1}}}; & r^n \triangleq \frac{P_{env}}{P^n} \leq r_c \\ F_{choke}^n \cdot \frac{\sqrt{(r^n)^{\frac{2}{k}} - (r^n)^{\frac{k+1}{k}}}}{\sqrt{r_c^{\frac{2}{k}} - r_c^{\frac{k+1}{k}}}}; & r_c < r^n \leq 1 \\ 0 & r^n > 1 \end{cases};$$

2. $h_N^n \triangleq h_N(T^n, \theta_0^n, P^n; \alpha) = \frac{k_N^n \cdot \overline{Nu_N^n}}{H}$; with

$$\overline{Nu_N^n} = \begin{cases} a \cdot (Gr_N^n \cdot Pr_N^n)^c, & \text{for } Gr_N^n \cdot Pr_N^n \leq 10^9; \quad \text{laminar} \\ c \cdot (Gr_N^n \cdot Pr_N^n)^d, & \text{for } Gr_N^n \cdot Pr_N^n \leq 10^9; \quad \text{turbulent} \end{cases}$$

$$Gr_N^n \triangleq \frac{g \cdot \beta_N^n \cdot (\rho_N^n)^2}{(\mu_N^n)^2} \cdot H^3 \cdot (\theta_0^n - T^n); \quad Pr_N^n \triangleq \frac{C p_N^n \cdot \mu_N^n}{k_N^n};$$

In the above expressions, the physical properties of nitrogen (i.e., k_N , β_N , ρ_N , μ_N , Cp_N) is denoted by γ_N , and is obtained by double interpolation (Petruzzi et al. 2010), as follows

$$\begin{aligned}\gamma_N^n &= \left(\gamma_N^{P_r}\right)^n + \frac{\left(\gamma_N^{P_{r+1}}\right)^n - \left(\gamma_N^{P_r}\right)^n}{P_{r+1} - P_r} \cdot (P^n - P_r); \quad P_r \leq P^n < P_{r+1}; \\ \left(\gamma_N^{P_i}\right)^n &= \gamma_N^{P_r, T_s} + \frac{\gamma_N^{P_r, T_{s+1}} - \gamma_N^{P_r, T_s}}{T_{s+1} - T_s} \cdot (\overline{T_N^n} - T_s); \quad T_s \leq \overline{T_N^n} < T_{s+1}; \\ \overline{T_N^n} &= \frac{T^n + \theta_0^n}{2}; \\ \gamma_N^{P_r, T_s} &= \gamma_N(\overline{T_N} = T_s, P = P_r)\end{aligned}$$

3. $h_A^n \triangleq h_A(\theta_j^n; \alpha) = \frac{k_A^n \cdot \overline{Nu_A^n}}{H}$; with

$$\begin{aligned}\overline{Nu_A^n} &= \begin{cases} a \cdot (Gr_A^n \cdot Pr_A^n)^b, & \text{for } Gr_A^n \cdot Pr_A^n \leq 10^9; \quad \text{laminar} \\ c \cdot (Gr_A^n \cdot Pr_A^n)^d, & \text{for } Gr_A^n \cdot Pr_A^n > 10^9; \quad \text{turbulent} \end{cases} \\ Gr_A^n &= \frac{g \cdot \beta_A^n \cdot (\rho_A^n)^2}{(\mu_A^n)^2} \cdot H^3 \cdot (T_{env} - \theta_j^n); \quad Pr_A^n = \frac{Cp_A^n \cdot \mu_A^n}{k_A^n};\end{aligned}$$

where the respective physical property of air (i.e., k_A , β_A , ρ_A , μ_A , Cp_A) is denoted by γ_A , and is obtained by linear interpolation (Petruzzi et al. 2010), as follows:

$$\begin{aligned}\gamma_A^n &= \gamma_A^{T_k} + \frac{\gamma_A^{T_{k+1}} - \gamma_A^{T_k}}{T_{k+1} - T_k} \cdot (\overline{T_A^n} - T_k); \quad T_k \leq \overline{T_A^n} < T_{k+1}; \quad \overline{T_A^n} = \frac{\theta_j^n + T_{env}}{2}; \\ \gamma_A^{T_k} &= \gamma_A(\overline{T_A} = T_k).\end{aligned}$$

The above discretized system can be conveniently solved by determining at the outset the gas pressure P^{n+1} and the gas temperature T^{n+1} from the first and second equations. Then, the remaining system becomes tridiagonal (Petruzzi et al. 2010), and is easily solvable for the unknown vector, θ_j^{n+1} , by a standard two-sweep method.

Typical measurements performed for the benchmark blowdown experiment ICI (Haque et al. 1992a, b; Petruzzi 2008) involve pressures and temperatures at given locations and instances in time. In order to use such measurements for calibrating the various system parameters, the responses (or results) computed by means of the mathematical model presented in the forgoing must correspond to the respective measurements. The most general mathematical representation of such a response is a functional of the system's parameters and state variables, of the form

$$R = \int_{t=0}^{t=t_f} F(P, T, \theta_0, \dots, \theta_j; \alpha) dt \quad (279)$$

where $F(P, T, \theta_0, \dots, \theta_j; \alpha)$ is a suitably defined function of the state variables $\mathbf{u}$ and of the system parameters α , while t_f denotes the time at which the simulated transient ends. For example, if the response of interest is the gas temperature, $T(\bar{t})$, at some point in time, $\bar{t}$, then $F(P, T, \theta_0, \dots, \theta_j; \alpha) \equiv T(t) \cdot \delta(t - \bar{t})$ where $\delta(t - \bar{t})$ is the Dirac-delta function.

Applying the general theory presented in Cacuci (2003) and Cacuci et al. (2005), the sensitivities of the response, R , to the model parameters, α , are given by the Gateaux-derivative, DR, along the (284-component) variational vector $\delta\alpha$ and the $(J+3)$ -component variational vector $\delta\mathbf{u} \triangleq \mathbf{h} \triangleq (h_p, h_T, h_{\theta_0}, \dots, h_{\theta_J})$. For the response defined in (279), the respective Gateaux-derivative, DR, is obtained as

$$\begin{aligned} DR &= \int_0^{t_f} \left[\left(\frac{\partial F}{\partial P} \right)^0 h_p + \left(\frac{\partial F}{\partial T} \right)^0 h_T + \left(\frac{\partial F}{\partial \theta_0} \right)^0 h_{\theta_0} + \dots + \left(\frac{\partial F}{\partial \theta_J} \right)^0 h_{\theta_J} \right] dt \\ &\quad + \int_0^{t_f} \left[\sum_{i=1}^{284} \left(\frac{\partial F}{\partial \alpha_i} \right)^0 \delta \alpha_i \right] dt = \int_0^{t_f} [(\tilde{N}_u F)^0 \mathbf{h}] dt + \int_0^{t_f} [(\tilde{N}_\alpha F)^0 (\delta \alpha)] dt \\ &\triangleq DR_i + DR_d \end{aligned} \quad (280)$$

The so-called “direct-effect” term, DR_d , is independent of the variations $\mathbf{h}$ and can be computed readily. However, the so-called “indirect-effect” term, DR_i , can be computed only after having determined the variational vector $\mathbf{h}$. This vector is the solution of the “forward sensitivity system” (also called “variational tangent model”) obtained by taking the Gateaux-derivatives of (273), computed at the nominal parameter values, along the variational vectors $\delta\alpha$ and $\delta\mathbf{u} \triangleq \mathbf{h} \triangleq (h_p, h_T, h_{\theta_0}, \dots, h_{\theta_J})$. Applying the general theory presented in Cacuci (2003) and Cacuci et al. (2005), the Gateaux-derivative of (273) yields the following forward sensitivity system:

$$\begin{aligned} \frac{dh_p}{dt} - \left(\frac{\partial N_1}{\partial P} \right)^0 h_p - \left(\frac{\partial N_1}{\partial T} \right)^0 h_T - \left(\frac{\partial N_1}{\partial \theta_0} \right)^0 h_{\theta_0} - \left(\frac{\partial N_1}{\partial \theta_J} \right)^0 h_{\theta_J} &= \sum_{i=1}^{284} \left(\frac{\partial N_1}{\partial \alpha_i} \right)^0 (\delta \alpha_i) \equiv q_1; \\ \frac{dh_T}{dt} - \left(\frac{\partial N_2}{\partial P} \right)^0 h_p - \left(\frac{\partial N_2}{\partial T} \right)^0 h_T - \left(\frac{\partial N_2}{\partial \theta_0} \right)^0 h_{\theta_0} - \left(\frac{\partial N_2}{\partial \theta_J} \right)^0 h_{\theta_J} &= \sum_{i=1}^{284} \left(\frac{\partial N_2}{\partial \alpha_i} \right)^0 (\delta \alpha_i) \equiv q_2; \\ -\frac{K_W}{\Delta x} (h_{\theta_1} - h_{\theta_0}) + \left[\left(\frac{\partial h_N}{\partial P} \right)^0 h_p + \left(\frac{\partial h_N}{\partial T} \right)^0 h_T + \left(\frac{\partial h_N}{\partial \theta_0} \right)^0 h_{\theta_0} \right] &= (\theta_0^0 - T^0) + (h_{\theta_0} - h_T) h_N^0 \\ &= \left[\frac{\delta K_W}{\Delta x} - \frac{K_W}{(\Delta x)^2} \delta(\Delta x) \right] (\theta_1^0 - \theta_0^0) - (\theta_0^0 - T^0) \sum_{i=1}^{284} \left(\frac{\partial h_N}{\partial \alpha_i} \right)^0 (\delta \alpha_i) \equiv q_3; \\ \frac{dh_{\theta_j}}{dt} - \frac{\lambda_w}{(\Delta x)^2} (h_{\theta_{j+1}} - 2h_{\theta_j} + h_{\theta_{j-1}}) &= (\theta_{j+1}^0 - 2\theta_j^0 + \theta_{j-1}^0) \left[\frac{\delta \lambda_w}{(\Delta x)^2} - \frac{2\lambda_w \delta(\Delta x)}{(\Delta x)^3} \right] \equiv q_{j+3}; \quad j = 1, \dots, J-1; \\ \frac{K_W}{\Delta x} (h_{\theta_j} - h_{\theta_{j-1}}) + \left(\frac{\partial h_A}{\partial \theta_j} \right)^0 (\theta_j^0 - T_{env}^0) h_{\theta_j} + h_A^0 h_{\theta_j} &= -(\theta_j^0 - \theta_{j-1}^0) \left[\frac{\delta K_W}{\Delta x} - \frac{K_W \delta(\Delta x)}{(\Delta x)^2} \right] - (\theta_j^0 - T_{env}^0) \sum_{i=1}^{284} \left(\frac{\partial h_A}{\partial \alpha_i} \right)^0 (\delta \alpha_i) + (\delta T_{env}) h_A^0 \equiv q_{J+3}; \end{aligned}$$

The above system is linear in $\mathbf{h}$ and can therefore be written in matrix form as

$$\mathbf{A}\mathbf{h} = \mathbf{q} \quad (281)$$

where the coefficients of the matrix $\mathbf{A}$ are operators containing Gateaux-derivatives with respect to the state variables $\mathbf{u}$, while the components of the vector $\mathbf{q}$ comprise operators containing Gateaux-derivatives with respect to the system parameters α . The explicit expressions of these Gateaux-derivatives are listed in Petruzzi et al. (2010). All of these quantities are evaluated at the nominal solution of the original system, $N(\mathbf{u}^0, \alpha^0) = \mathbf{0}$, as indicated by the superscript “zero” attached to the respective quantities.

The initial conditions for (281) are obtained by taking the Gateaux-derivatives of (274), yielding:

$$h_p(0) = \delta P_0; \quad h_T(0) = \delta T_0; \quad h_{\theta_j}(0) = \delta T_{env} = \delta T_0; \quad j = 1, \dots, J-1. \quad (282)$$

The time-dependent profiles of the sensitivities of the system's state variables to each of the $I = 284$ parameters α_i can be obtained by repeatedly solving (281) and (282), for each parameter variation, $\delta\alpha_i$, to obtain the corresponding vector $\mathbf{h}$. In turn, $\mathbf{h}$ is used in (280) to compute the corresponding sensitivity DR . This procedure is customarily called the *forward sensitivity analysis procedure (FSAP)*. Alternatively, the need to calculate $\mathbf{h}$ for each parameter variation $\delta\alpha_i$ can be circumvented by using the *adjoint sensitivity analysis procedure (ASAP)* (Cacuci 2003; Cacuci et al. 2005) to express the indirect-effect term in (280) in terms of an appropriately defined adjoint function $\mathbf{u}^* \triangleq (P^*(t), T^*(t), \theta_0^*(t), \dots, \theta_J^*(t))$, such that

$$DR_i = \int_0^{t_f} (\mathbf{u}^* \cdot \mathbf{q}) dt - \left[\int_0^{t_f} (\mathbf{u}^* \cdot \mathbf{A}\mathbf{h} - \mathbf{h} \cdot \mathbf{A}^* \mathbf{u}^*) dt \right] \quad (283)$$

where $\mathbf{A}^*$ is the adjoint of the matrix-valued operator $\mathbf{A}$, and the adjoint function $\mathbf{u}^*$ is the solution of the operator equation

$$\mathbf{A}^* \mathbf{u}^* = \nabla_{\mathbf{u}} F \quad (284)$$

subject to the final time conditions

$$P^*(t_f) = 0; \quad T^*(t_f) = 0; \quad \theta_j^*(t_f) = 0; \quad j = 1, \dots, J-1. \quad (285)$$

Evaluating the second integral in (283) leads to the following for the indirect term DR_i :

$$DR_i = \int_0^{t_f} \left[P^* q_1 + T^* q_2 + \sum_{j=0}^J \theta_j^* q_{3+j} \right] dt + P^*(0) \delta P_0 + T^*(0) \delta T_0 + \sum_{j=1}^{J-1} \theta_j^*(0) \delta T_{env}. \quad (286)$$

It is convenient to change independent variables in (284) from t to $\tau \triangleq t_f - t$, thereby transforming that final-time value problem into the following initial-value problem in τ :

$$\begin{aligned}
 \frac{dP^*}{d\tau} &= \left(\frac{\partial F}{\partial P} \right)_\tau^0 + \left(\frac{\partial N_1}{\partial P} \right)_\tau^0 P^*(\tau) + \left(\frac{\partial N_2}{\partial P} \right)_\tau^0 T^*(\tau) - \left(\frac{\partial h_N}{\partial P} \right)_\tau^0 (\theta_0^* - T^0)_\tau \theta_0^*(\tau) \\
 \frac{dT^*}{d\tau} &= \left(\frac{\partial F}{\partial T} \right)_\tau^0 + \left(\frac{\partial N_2}{\partial T} \right)_\tau^0 T^*(\tau) + \left(\frac{\partial N_1}{\partial T} \right)_\tau^0 P^*(\tau) - \left[\left(\frac{\partial h_N}{\partial T} \right)_\tau^0 (\theta_0^* - T^0)_\tau - h_N^0(\tau) \right] \theta_0^*(\tau) \\
 0 &= \left(\frac{\partial F}{\partial \theta_0} \right)_\tau^0 + \left(\frac{\partial N_1}{\partial \theta_0} \right)_\tau^0 P^*(\tau) + \left(\frac{\partial N_2}{\partial \theta_0} \right)_\tau^0 T^*(\tau) \\
 &\quad - \left[\left(\frac{\partial h_N}{\partial \theta_0} \right)_\tau^0 (\theta_0^* - T^0)_\tau + h_N^0(\tau) + \frac{K_W}{\Delta x} \right] \theta_0^*(\tau) + \frac{\lambda_w}{(\Delta x)^2} \theta_1^*(\tau); \\
 \frac{d\theta_1^*}{d\tau} &= \left(\frac{\partial F}{\partial \theta_1} \right)_\tau^0 + \frac{K_W}{\Delta x} \theta_0^*(\tau) - \frac{2\lambda_w}{(\Delta x)^2} \theta_1^*(\tau) + \frac{\lambda_w}{(\Delta x)^2} \theta_2^*(\tau) \\
 \frac{d\theta_j^*}{d\tau} &= \left(\frac{\partial F}{\partial \theta_j} \right)_\tau^0 + \frac{\lambda_w}{(\Delta x)^2} \theta_{j-1}^*(\tau) - \frac{2\lambda_w}{(\Delta x)^2} \theta_j^*(\tau) + \frac{\lambda_w}{(\Delta x)^2} \theta_{j+1}^*(\tau); \quad j = 2, \dots, J-2; \\
 \frac{d\theta_{J-1}^*}{d\tau} &= \left(\frac{\partial F}{\partial \theta_{J-1}} \right)_\tau^0 + \frac{\lambda_w}{(\Delta x)^2} \theta_{J-2}^*(\tau) - 2 \frac{\lambda_w}{(\Delta x)^2} \theta_{J-1}^*(\tau) + \frac{K_W}{\Delta x} \theta_J^*(\tau) \\
 0 &= \left(\frac{\partial F}{\partial \theta_J} \right)_\tau^0 + \left(\frac{\partial N_1}{\partial \theta_J} \right)_\tau^0 P^*(\tau) + \left(\frac{\partial N_2}{\partial \theta_J} \right)_\tau^0 T^*(\tau) + \frac{\lambda_w}{(\Delta x)^2} \theta_{J-1}^*(\tau) \\
 &\quad - \left[\frac{K_W}{\Delta x} + \left(\frac{\partial h_A}{\partial \theta_J} \right)_\tau^0 (\theta_J^* - T_{env}^0)_\tau + h_A^0(\tau) \right] \theta_J^*(\tau) \\
 P^*(0) &= 0; \quad T^*(0) = 0; \quad \theta_j^*(0) = 0 \quad j = 1, \dots, J-1
 \end{aligned}$$

Note that the adjoint sensitivity system is independent of any parameter variations $\delta\alpha_i$. Therefore, it needs to be solved only once for every response considered, thereby reducing significantly the computational costs, when the number of responses of interest is smaller than the number of parameters α_i . Note that the variation $DR_{j,i}$ of the generic response R_j to the variation $\delta\alpha_i$ of the parameter α_i yields the absolute respective sensitivity; the corresponding relative sensitivity is defined as:

$$s_{j,i} = \frac{\alpha_i}{R_j} \cdot \frac{DR_{j,i}}{\delta\alpha_i} \quad (287)$$

The experiment IC1 was performed using 100 mole-% of nitrogen (at the nominal parameter values listed in ► Table 4), in a vertical cylinder with flat ends having the following dimensions: length = 1.524 m, inside diameter = 0.273 m, and wall thickness = 25 mm. Starting from an initial pressure of 150 bar and initial temperature of 290 K, the nitrogen was released from the top through a choke of equivalent diameter 6.35 mm. The blowdown time was ca. 100 s, and there was no liquid formation by condensation from the gas. The experiment was conducted in a bunker; the air surrounding the experiment was stagnant at 1.01 bars and 290 K. Several thermocouples for measuring the fluid and the wall temperatures during the blowdown transient were located at various spatial positions; the corresponding experimental error bands, at several instants in time, are listed in ► Table 5.

■ Table 4

Nominal parameter values for experiment IC1

#	Component		Description	ID	Value	Unit
1	Vessel	Input	Height	H	152.4	cm
2			Internal diameter	D	27.3	cm
3			Wall thickness	S	2.5	cm
4			Wall thermal cond.	K_w	14.42	W/m·K
5			Wall thermal diff.	λ_w	4.50×10^{-6}	m ² /s
6		Derived	Volume	V	89207.25	cm ³

23	Numerical parameters		Time step	Δt	0.1	s
24			Mesh size	Δx	0.25	cm

*: The initial system conditions are assumed to be stationary.

The benchmark blowdown experiment IC1 was simulated numerically for the nominal parameter values shown in ► Table 4, using the discretized mathematical model (278). ► Figure 8 presents comparisons between the experimental and computational results for the gas pressure, while ► Fig. 9 presents the comparison between computational and experimental results for the gas and vessel wall temperatures, including the respective experimental uncertainty bands. As depicted in ► Fig. 8, the computed results for the gas pressure are practically indistinguishable from the experimental results for the first 20 s but display a slight deviation from the experimental data after 20 s. The computed evolution of the vessel's surface temperature in contact with the gas (internal vessel wall) also shows excellent agreement with the experimental data, practically coinciding with the upper experimental curve, as shown

■ Table 5
Error bands for gas pressure and gas/wall temperatures

Time (s)	Experimental error bands (upper-lower)		
	Gas pressure (bar)	Gas temperature (K)	Wall temperature (K)
0		1	1
10		6	3
20		16	5
30		16	6
40	2.0*	20	6
60		23	6
80		28	6
100		27	5

* ±1 bar has been assumed due to the digitalization process by which the experimental values of the gas pressure have been derived.

■ Figure 8
Benchmark experiment IC1: measured and computed pressure

■ **Figure 9**
Benchmark experiment IC1: measured and computed temperature

in ► Fig. 9. This figure also shows that the computed gas temperature lies within the region spanned by the two experimental curves, even though the computed results tend toward the upper (experimental) uncertainty band during the time span between 15 and 30 s. These comparisons provide credible evidence in support of both the verification and validation of the numerical model (278).

Since the vessel walls are very thin, the discretization parameter Δx need not be considered as uncertain, so that the total number of uncertain parameters is $N_\alpha = 281 + 2 = 283$ (where the '+2' is referring to the two initial boundary conditions for the gas pressure P_0 and gas temperature T_0 model parameters), as follows:

$$\alpha = \left\{ D, H, S, A, C_d, T_{env}, P_{env}, a, b, c, d, k, R, \lambda_w, K_w, g, \rho_{N,P_r,T_s}, Cp_{N,P_r,T_s}, \dots \right. \\ \left. \dots, k_{N,P_r,T_s}, \mu_{N,P_r,T_s}, \beta_{N,P_r,T_s}, \rho_{A,T_k}, Cp_{A,T_k}, k_{A,T_k}, \mu_{A,T_k}, \beta_{A,T_k}, P_0, T_0 \right\}$$

Response sensitivities to parameters were computed using both the forward sensitivity (“variational tangent”) model and the adjoint sensitivity model, and the complete results are presented in Petruzzi et al. (2010). In particular, ► Figs. 10 and 11 depict time-dependent sensitivity profiles of the gas pressure and temperature, respectively, to the most important parameters. As shown in these figures, the gas pressure is most sensitive initially to internal diameter of the vessel, D , followed by the sensitivities to the vessel’s height H , the orifice discharge coefficient, C_d , and the initial conditions (P_0 and T_0). On the other hand, the gas temperature is initially (for ca. 20 s) most sensitive to T_0 , but the sensitivity to the coefficient d in the Nusselt correlation becomes dominant later. The various time-dependent graphs in ► Figs. 10 and 11 highlight clearly the fact that several important sensitivities change sign during the transient.

Figure 10
Time-dependent profiles of largest sensitivities for gas pressure

Figure 11
Time-dependent profiles of largest sensitivities for gas temperature

In addition to verifying and validating the software modules for computing the state variables (pressures and temperatures), both the forward sensitivity and the adjoint sensitivity models were verified by using the first-order Taylor expansion

$$\left[R(\mathbf{u}^0 + \mathbf{h}; \alpha_i^0 + \delta\alpha_i) - R(\mathbf{u}^0; \alpha_i^0) \right] / \delta\alpha_i = DR(\mathbf{u}^0, \alpha^0; \mathbf{h}, \delta\alpha_i) + O[(\delta\alpha_i)^2] \quad (288)$$

The left side of the above expression was obtained by recomputations using the nonlinear model, by varying the parameters α_i , one at a time, by 1% around their nominal values listed in [Table 4](#). The sensitivities on the right side of (288) were computed by using both the forward and the adjoint sensitivity models. For such small (1%) parameter variations, the response varies linearly with the respective parameter variations. Therefore, the agreement (or disagreement) between the left- and right-sides of (288) provides a verification that the respective numerical procedures have been implemented correctly (or not) in both the forward and adjoint sensitivity models for computing sensitivities. [Figure 12a–d](#) depict comparisons between recomputations and sensitivities calculated using the forward and adjoint sensitivity models, for the parameter k . Such good agreements were typical for this experiment, thus lending support to “model verification,” indicating that the numerical procedures for computing sensitivities were correctly implemented in both the forward and adjoint sensitivity models. Typical nonlinear effects are displayed in [Fig. 12d](#), where the sensitivities computed by the forward and the adjoint methods agree with one another, but both deviate (by roughly 0.1%) from recomputations at times beyond ca. 70 s.

For this benchmark experiment, all parameters are uncorrelated constants, assumed to be normally distributed, with standard deviations (taken as the respective 95%-probability values) as shown in [Table 6](#). Therefore, the parameter covariance matrix will initially

Description	Parameters	Uncertainty (%)
Geometrical parameters, linear	D, H, S	0.1
Geometrical parameters, area	A	0.2
Discharge coefficient	C_d	10.0
Gas and wall temperatures	T_o, T_{env}	0.17
Gas pressures	P, P_{env}	0.13
Code correlations (HTC)	a, b, c, d	2.0
Wall properties	λ_w, K_w	2.0
Nitrogen and air density	$\rho_{N,P,T_s}, \rho_{A,T_k}$	0.02
Nitrogen and air heat capacity	$C_{p_{N,P,T_s}}, C_{p_{A,T_k}}$	0.3
Nitrogen and air thermal conductivity	k_{N,P,T_s}, k_{A,T_k}	2.0
Nitrogen and air viscosity	$\mu_{N,P,T_s}, \mu_{A,T_k}$	2.0
Nitrogen and air expansion coefficient	$\beta_{N,P,T_s}, \beta_{A,T_{ks}}$	2.0

(i.e., at time $t = 0$) be time-independent, with the following structure:

$$C_{\alpha} = \begin{pmatrix} \bar{C}_{\alpha} & \bar{C}_{\alpha} & \cdots & \bar{C}_{\alpha} \\ \bar{C}_{\alpha} & \bar{C}_{\alpha} & \cdots & \bar{C}_{\alpha} \\ \vdots & \vdots & \ddots & \vdots \\ \bar{C}_{\alpha} & \bar{C}_{\alpha} & \cdots & \bar{C}_{\alpha} \end{pmatrix}; \quad \bar{C}_{\alpha} \triangleq \text{diag}[\text{var}(\alpha_i)].$$

The covariance matrix for the computed responses, $C_{rc}(\alpha^0)$, is obtained by combining the above parameter covariance matrix with the parameter sensitivities according to the “sandwich formula” (230), repeated below for convenience:

$$C_{rc}(\alpha^0) \triangleq \langle \delta r \delta r^{\dagger} \rangle = [S(\alpha^0)] \langle \delta \alpha \delta \alpha^{\dagger} \rangle [S(\alpha^0)]^{\dagger} = [S(\alpha^0)] C_{\alpha} [S(\alpha^0)]^{\dagger}. \quad (230)$$

► **Figures 13a–15** present results that illustrate the wealth of information contained in the final form of the response covariance matrix. For example, ► **Fig. 13a–f** display time-dependent standard deviations for several computed responses (gas pressure and temperature, mass inventory, internal wall temperature, and internal and external heat transfer coefficients, respectively). Noteworthy in ► **Fig. 13f** is the jump-discontinuity in the nominal value and computed uncertainties in the heat transfer coefficient to the external wall; this discontinuity is due to the transition from laminar to turbulent regime. ► **Figure 14a–d** depict time evolution of correlations between several responses (i.e., gas pressure, gas and wall temperatures, mass flow rate, etc.) at various time instants (10 s, 50 s, 70 s, and 90 s). These snapshots show that the responses, which are uncorrelated at the initial time, become weakly correlated as time progresses, except for the heat transfer coefficients and break area, which become somewhat stronger correlated beyond ca. 70 s. These time correlations arise due to the time-dependent sensitivities that appear

■ **Figure 13a**

Time-dependent variance of computed gas pressure, due to parameter uncertainties

■ Figure 13b

Time-dependent variance of mass inventory, due to parameter uncertainties

as the weighting functions in the “sandwich formula” given by (230). ➤ Figures 15a–d depict the time evolution of correlations between selected pairs of responses, indicating that:

The gas temperature is anti-correlated with the mass flow rate at the beginning and end of the transient, but is positively correlated during the time interval between ca. 20 and 60 s;

The gas pressure is positively correlated with the gas temperature trough almost all of the transient becoming anti-correlated at the very the end of the transient; and

Figure 13d

Time-dependent variance of internal vessel wall temperature, due to parameter uncertainties

Figure 13e

Time-dependent variance of internal heat transfer coefficient, due to parameter uncertainties

The gas pressure is time-wise correlated and time-wise anti-correlated with the mass inventory and mass flow rate, respectively.

The assimilation of experimental data from the blowdown experiment in ICI for obtaining best-estimate predicted parameters, responses, and corresponding reduced uncertainties were performed by using the “two-step” “on-line” formulas derived in (259–263). Furthermore, since the model parameters are uncorrelated to the measured responses in the blowdown experiment

Figure 13f
Time-dependent variance of external heat transfer coefficient, due to parameter uncertainties

Figure 14a
Computed responses relative covariances at 10 s

Figure 14b
Computed responses relative covariances at 50 s

in IC1, these general formulas become significantly simpler by setting $C_{r\alpha}^{v\mu} = 0$. Thus, the specific formulas used for the data assimilation/predictive estimation for the experiment IC1 are as given below:

Best-estimate values for model parameters:

$$\left(\alpha^{be}\right)^k = \left(\alpha^0\right)^k - \sum_{\mu=k-1}^k \left\{ \left[\sum_{\rho=k-1}^{\mu} C_{\alpha}^{k\rho} \left(s^{\dagger}\right)^{\mu\rho} \right] \left[\sum_{\eta=k-1}^k K_d^{\mu\eta} d^{\eta} \right] \right\}, \quad k = 1, 2, \dots, N_t. \quad (289)$$

Best-estimate values for responses:

$$\left(r^{be}\right)^k = \left(r_m\right)^k + \sum_{\mu=k-1}^k \left\{ \left[C_m^{k\mu} \right] \left[\sum_{\eta=k-1}^k K_d^{\mu\eta} d^{\eta} \right] \right\}, \quad k = 1, 2, \dots, N_t. \quad (290)$$

Best-estimate parameter covariances:

$$\left(C_{\alpha}^{be}\right)^{v\mu} = C_{\alpha}^{v\mu} - \sum_{\eta=k-1}^k \sum_{\rho=k-1}^k \left[\sum_{\pi=k-1}^{\rho} C_{\alpha}^{v\pi} \left(s^{\dagger}\right)^{\rho\pi} \right] K_d^{\rho\eta} \left[\sum_{\pi=k-1}^{\eta} s^{\eta\pi} C_{\alpha}^{\pi\mu} \right] \quad (291)$$

for $v = k-1, k$; and $\mu = k-1, k$; $k = 1, 2, \dots, N_t$.

Figure 14c
Computed responses relative covariances at 70 s

Best-estimate response covariances:

$$\left(C_{\alpha}^{be}\right)^{v\mu} = C_{\alpha}^{v\mu} - \sum_{\eta=k-1}^k \sum_{\rho=k-1}^k \left[\sum_{\pi=k-1}^{\rho} C_{\alpha}^{v\pi} \left(s^{\dagger}\right)^{\rho\pi} \right] K_d^{\rho\eta} \left[\sum_{\pi=k-1}^{\eta} s^{\eta\pi} C_{\alpha}^{\pi\mu} \right] \quad (292)$$

for $v = k-1, k;$ and $\mu = k-1, k;$ $k = 1, 2, \dots, N_t.$

Best-estimate parameter–response covariances:

$$\left(C_{ra}^{be}\right)^{v\mu} = \sum_{\eta=k-1}^k \sum_{\rho=k-1}^k C_m^{v\rho} K_d^{\rho\eta} \sum_{\pi=k-1}^{\eta} s^{\eta\pi} C_{\alpha}^{\pi\mu} \quad (293)$$

for $v = k-1, k;$ and $\mu = k-1, k;$ $k = 1, 2, \dots, N_t.$

Typical best-estimate values and uncertainty bands are presented in ► Fig. 16a, b for the gas pressure and temperature responses, respectively. These results were obtained following the assimilation of 20 experimental measurements taken at the time steps indicated in the respective figures. The value of “ χ^2 per degree of freedom” was close to unity for both of these data assimilation applications, thus indicating consistency among the parameters and the respective measured and computed responses. As depicted in ► Fig. 16a, b, the calibration procedure

Figure 14d
Computed responses relative covariances at 90 s

Figure 15a
Time evolution of relative covariances (normalized respect to response value at time 0) between the gas pressure and gas temperature responses

■ Figure 15b

Time evolution of relative covariances (normalized respect to response value at time 0) between the gas pressure and mass flow rate responses

■ Figure 15c

Time evolution of relative covariances (normalized respect to response value at time 0) between the gas temperature and mass flow rate responses

moves the values of the best-estimate responses (blue curves) toward the measured values, as would be expected for this benchmark experiment, which has measurement uncertainties smaller than the computed response uncertainties (due to parameter uncertainties). Furthermore, the calibration procedure clearly reduces best-estimate upper and, respectively lower uncertainty bands for both the gas pressure and temperature responses, in agreement with the reduction of variance values (i.e., the diagonal elements) from the matrix C_m to C_r^{be} , as

Figure 15d
Time evolution of relative covariances (normalized respect to response value at time 0) between the gas pressure and mass inventory responses

Figure 16a
Best-estimate calibrated values and uncertainty bands for the gas pressure following data assimilation/model calibration

expressed by (292). The reduction in the best-estimate predicted uncertainties is much larger for the gas pressure (since the measurement uncertainties for this quantity are very small) than for the gas temperature (for which the experimental uncertainties are comparatively larger). The largest variations in time experienced by the best-estimate calibrated parameters and their corresponding calibrated variances are presented in ► Fig. 17a, b, illustrating typical

Figure 16b
Best-estimate calibrated values and uncertainty bands for the gas temperature following data assimilation/model calibration

Figure 17a
Largest time variations of predicted best-estimate parameter values following data assimilation/model calibration

Figure 18

Illustrative uncertainty reduction: comparison of the time-dependent relative covariances (normalized respect to response value at initial time) between the gas pressure and temperature, before and after data assimilation/model calibration

results obtained by consistent data assimilation. The reduction in the best-estimate uncertainty obtained after consistent data assimilation is illustrated in [Fig. 18](#) for the gas pressure, which highlights the significant reduction in the magnitudes of the uncertainties on the anti-diagonal of the respective relative covariance matrices.

7 Model Validation and Calibration: Concluding Remarks and Open Issues

As has been discussed throughout this chapter, the results of experiments seldom coincide in practice with the computational results obtained from the mathematical models of the respective experiments. Such discrepancies between experimental and computational results provide the basic motivation for performing quantitative *model verification*, *validation*, *qualification*, and *predictive estimation*. The need for the evaluation of uncertainty associated with the prediction of computer codes in nuclear reactor safety technology is mandatory when using the so-called “*best estimate codes*” in the licensing process and for *safety analyses* (see, e.g., U. S. Nuclear Regulatory Commission 2005; International Atomic Energy Agency 2008). Several international activities addressing the current state-of-the-art methods for evaluating and predicting uncertainties in reactor thermal hydraulics and safety have been completed or are ongoing (Wickett et al. 1998; OECD/NEA 2007; Chauliac et al. 2009). The robustness of the traditional method for propagating model input errors to obtain errors in the model’s outputs, typified by the CSAU (Code Scaling and Applicability Uncertainty) method (Boyack et al. 1990), has been improved (Hofer 1993) by using Wilks’ statistical results (Wilks 1941). Nevertheless, coupling between system codes (e.g., thermal hydraulics and three-dimensional neutron kinetics codes) provides additional challenges to uncertainty analysis methods, as illustrated by the ongoing international assessment within the OECD/NEA UAM (Uncertainty Assessment Method) project (OECD/NEA 2007).

Although the above-mentioned methods have been continually improved from a computational standpoint, the incomplete and user-dependent (Aksan et al. 1995) results obtained by using them in practice provide a strong motivation for developing alternative methods that are mathematically more rigorous and, hence, less prone to subjective application and interpretation. Such methods must comprise the following activities: model verification, model validation and qualification, and predictive estimation. Loosely speaking, “*model verification*” means “are you solving the mathematical model correctly?” Model verification involves activities that are related to software quality assurance (SQA) practices and to activities directed toward finding and removing deficiencies in numerical algorithms used to solve partial differential equations (PDEs). SQA procedures are needed during software development and modification, as well as during production computing. SQA procedures are well developed in general, but areas of improvement are needed with regard to software operating on massively parallel computer systems. *Numerical algorithm verification* (NAV) addresses the software reliability of the implementation of all the numerical algorithms that affect the numerical accuracy of solutions produced by the code. Numerical algorithm verification is conducted by comparing computational solutions with benchmark solutions: analytical solutions, manufactured solutions, and highly accurate numerical solutions. Solution verification, also called *numerical error estimation*, deals with the quantitative estimation of the numerical accuracy obtained when PDEs are solved using discretization methods. The primary goal in solution verification is the estimation of the numerical accuracy of all of the solution quantities of interest in a given simulation. Solution verification is related to the topic of *adaptive mesh refinement* (AMR), although the goals of AMR are more restrictive than those of solution verification. The discretization errors must be quantified in order to separate them, in principle, from other error and uncertainty sources, such as physics modeling errors and variability in physical properties. Two major shortcomings affect current verification methods, namely: (1) estimating discretization errors using solutions

on multiple mesh resolutions is a computationally expensive process, and (2) current methods for complex physics simulations are not robust.

Model validation means “does the model represent reality?” Specifically, model validation emphasizes the quantitative assessment of computational model accuracy by comparison with high-quality *validation experiments* – that is, experiments that are well characterized in terms of measurement and documentation of all the input quantities needed for the computational model, including carefully estimated and documented experimental measurement uncertainties. These validation experiments can be conducted on hardware that represents any level of simplification or disassembly of the actual, or complete, system of interest (for example, even experiments conducted on simple geometries with only one element of physics occurring). The state-of-the-art in model validation addresses issues of: (1) assessing model accuracy when several system response quantities have been measured and compared, and (b) comparing system response quantities from multiple realizations of the experiment with computational results that are characterized by probability distributions. Model validation emphasizes assessing the accuracy of physics-based models in blind comparisons with experimental data, a goal that is complementary to the goal of predictive capability in modeling and simulation.

Model qualification means certifying that a proposed simulation/design methodology/system satisfies all performance and safety specifications. Validation and qualification can be done only by selected benchmarking, taking into account systematically (i.e., using sensitivities) all of the uncertainties (computational, experimental, etc.). Verification and predictive validation must be based on a well-established set of scientific approaches that will allow the *a priori* announcement of quantified computational uncertainties. Model validation encompasses issues of quantifying model accuracy when several system response quantities have been measured and compared, and comparing system response quantities from multiple realizations of the experiment with computational results that are characterized by probability distributions. For this purpose, it is essential to construct a *parameter importance ranking table (PIRT)* which ranks, hierarchically, the importance of parameters, physical processes, and interactions of processes for all tiers and faces of the validation process, from single-effects benchmarks to system-level comparisons. The availability of response sensitivities, in addition to uncertainties, is paramount for constructing the *PIRT*.

Implementation of validation procedures for computations and experiments needed for model verification and validation is neither inexpensive nor easy. However, the quality of the verification and validation processes will be improved with each included step, resulting in increased confidence in the modeling and simulation capability. It is important to note that *verification and validation* is a process, *not a product*.

For improving the verification and validation processes, it is useful to attempt to define what ideal processes should be and assess practical difficulties in reaching these, as exemplified in the following:

Ideally, the application domain for the modeling and simulation capability under consideration would be well defined, with known accuracy requirements. Often, however, only some parts of the application domain are understood and some of the accuracy requirements are known.

Ideally, the validation tier hierarchy (from single-effect benchmarks to coupled system-level benchmarks) would be well established. Often, however, the validation hierarchy is known for individual subsystems or components, but the interactions between subsystems remain to be analyzed.

Ideally, the *PIRT* (*parameter importance ranking table*) has been constructed (quantitatively using all of the required sensitivities and uncertainties) and employed to rank the importance of physical processes and interactions of processes for all tiers of the validation hierarchy.

Ideally, the results of the *PIRT* would be used to define and prioritize code verification and validation activities, including corresponding schedules and needed resources. Often, however, the available resources rather than the *PIRT* dictate the schedule and priorities of code verification and validation, eliminating many possible verification and validation activities.

Ideally, the *SQA* procedures would have been defined, implemented, and documented. Often, however, *SQA* procedures are incompletely defined, partially implemented, adhered to just before a new code release, and informally documented.

Ideally, highly converged numerical solutions, in both space and time, would be obtained for every validation experiment conducted. Often, however, quantitative numerical error estimates are computed for some validation experiments, but some complex-system experiments only have qualitative error estimates.

Ideally, validation-experiment data would be well characterized, and a large number of experimental realizations would be available for estimating random and systematic (bias) errors. Often, however, only a few experimental realizations are available, and the respective experimental data is incompletely characterized.

Ideally, the validation metrics would be precisely defined (using statistical data for both computational and experimental results) and clearly connected to the modeling and simulation requirements for the respective application domain. Often, however, validation metrics and requirements are incompletely characterized, even for high-level system responses, and are lacking for low-level-tier physical response.

Ideally, the results and lessons learned from all of the validation activities would be clearly formulated, documented, and broadly communicated. Often, however, the results and lessons learned are documented only for “successful” validation experiments.

Predictive estimation (PE) comprises three key elements: *model calibration*, *model extrapolation*, and *estimation of the validation domain*. The result of the PE analysis is a probabilistic description of possible future outcomes based on all recognized errors and uncertainties. *Model calibration* addresses the integration of experimental data for the purpose of updating the data of the computational model. *Model extrapolation* addresses the prediction uncertainty in new environments or conditions of interest, including both untested parts of the parameter space and higher levels of system complexity in the validation hierarchy. Extrapolation of models and the resulting increase of uncertainty are poorly understood, particularly the estimation of uncertainty that results from nonlinear coupling of two or more physical phenomena that were not coupled in the existing validation database.

The *estimation of the validation domain* of the physics underlying the models of interest requires estimation of contours of constant uncertainty in the high-dimensional space that characterizes the application of interest. In practice, this involves the identification of areas where the predictive estimation of uncertainty meets specified requirements for the performance, reliability, or safety of the system of interest. The state-of-the-art in estimation of the validation domain is very early in both the conceptual and mathematical development. Developing predictive experimentally validated “best-estimate” numerical models is particularly important for designing new technologies and facilities based on novel processes, while striving to avoid, as much as possible, the costly and lengthy procedures of building representative mock-up experiments which might confirm – but would not necessarily explain – the predictions of

simulation tools. For example, the performance of fuels and materials, in particular fuel irradiation behavior, is dominated by the coupled effects of several phenomena and relies uniquely on very expensive and time-consuming confirmatory mockup experiments (e.g., multiyear irradiations), with little or no predictive capability; improvements in this regard have very high potential payoff. Also, systems-level analysis tools are, by nature, primarily predictive because they are evaluating systems that typically do not exist. When coupled phenomena occur, in particular for safety analyses, validation has been restricted to either mockup or component-level experimental comparison, with little predictive capability.

The most important activity in predictive estimation (PE) is *model calibration*, since the other two ingredients of PE could not be performed without the availability of a consistently calibrated model (in this context, “model” refers to the largest set of codes under consideration). The model calibration activity commences by identifying and characterizing errors and/or uncertainties from all steps in the sequence of modeling and simulation processes involved in a computational model prediction, including at least the following:

Data error or uncertainty (input data such as cross sections, model parameters such as reaction-rate coefficients, initial conditions, boundary conditions, and forcing functions such as external loading);

Model uncertainties: correlations, numerical discretization errors stemming from solution schemes, model options, incomplete modeling, simplified assumptions and approximations, uncertainty stemming from lack of knowledge about the physical processes being modeled;

Representation uncertainties: imperfect representation of facility geometry, higher dimensional (3D) effects, control, and system simplifications;

Scaling uncertainties: prototypes typically characterized by different geometric dimensions and materials (including working fluids), ranges of variation for thermal-hydraulic quantities usually differ (in prototypes) from full-scale plants;

Plant data uncertainties: unavailability of some plant parameters, instrument errors, and uncertainty in instrument response;

User effects, which are often implicitly present in all of the above-mentioned broad classes of uncertainties.

The mathematical framework for model calibration is provided by the *data adjustment and data assimilation* procedure. A state-of-the-art mathematical framework for data assimilation and model calibration for a generic time-dependent system was presented in ► Sect. 6. The basic premise underlying this mathematical framework is that only first- and second-order information (i.e., means and covariance matrices) is *a priori* available, which is actually the case in most practical situations, particularly when large-scale systems are involved. When only first and second moments of model parameters and experimental responses are available, the maximum entropy principle of statistical mechanics was employed in conjunction with information theory to construct a Gaussian prior distribution that takes all of the available information into account while minimizing (in the sense of quadratic loss) the introduction of spurious information. This prior distribution comprises also any correlations among model parameters and responses, thus generalizing the state-of-the-art data assimilation algorithms used in the geosciences (Kalnay 2003; Lewis et al. 2006).

The posterior distribution for the best-estimate calibrated model parameters and responses was constructed by using Bayes’ theorem. The best-estimate predicted mean values and reduced covariances, which are customarily needed when employing decision theory under “quadratic loss,” were computed by extracting the bulk contributions via the saddle-point method. In particular, this procedure yields the same Gaussian posterior distribution as would be obtained by

using the maximum likelihood method. The minimum value of the quadratic form appearing in the exponent of the Gaussian posterior distribution also provides the “ χ^2 of the calibration (adjustment) at hand.” This quadratic form can therefore be used as an indicator of the agreement between the computed and experimentally measured responses, indicating essentially the consistency of the measured responses with the model parameters. When all information is consistent, the posterior probability density function yields reduced best-estimate uncertainties for the best-estimate model parameters and responses, as illustrated for the paradigm benchmark time-dependent thermal-hydraulic system described in ➤ Sect. 6.4.

The model calibration methodology presented in this work provides a rigorous mathematical foundation for similar methodologies used in geophysical sciences (Kalnay 2003; Lewis et al. 2006), while extending these methodologies in the following directions:

Treatment of systems involving correlated parameters and responses (as opposed to no parameter–response correlations, e.g., in geophysical sciences);

Simultaneous calibration of all parameters and responses (as opposed to just initial conditions, as usually performed in geophysical sciences);

Simultaneous calibration over all time intervals; the usual two-step time advancement procedures used in geophysical sciences simply becomes a consequence, as a particular case, of the general methodology presented in this work.

From a computational point of view, the most intensive aspect of the data assimilation and model calibration methodology (cf. ➤ Sect. 6) is the computation of the sensitivities of responses to model parameters; these sensitivities play a fundamental role as weighting functions in all of the expressions for the best-estimated predicted values for parameters, responses, and their associated best-estimated reduced uncertainties. For large-scale systems, the most efficient method for computing these sensitivities is the *adjoint sensitivity procedure* (ASAP), as detailed in Cacuci et al. (2005, 2010) and Cacuci (2003). Note though, that the development of the adjoint sensitivity models underlying ASAP is far from trivial, and, as generally discussed in Cacuci et al. (2005) and Cacuci (2003), could benefit significantly from further theoretical and computational advances, including the class of methods collectively known under the name of *reduced-order modeling*. The other computationally intensive aspect in the assimilation and calibration methodology (cf. ➤ Sect. 6) is the inversion of the covariance matrix $C_d(\alpha^0)$ associated with the vector $d \triangleq R(\alpha^0) - r_x$, which measures the deviations between the respective computed and experimentally measured responses. Methods for efficiently inverting this matrix, as well as for reducing its dimension through “reduced-order modeling” using proper orthogonal decomposition methods are of substantial interest.

The best-estimate calibrated values for model parameters obtained through the application of the mathematical framework presented in ➤ Sect. 6 can also be used to estimate quantitatively the validation domain of the model under consideration, by computing *contours of constant best-estimate uncertainties in the high-dimensional parameter-space*. The best-estimate calibrated values can also be used to perform “model extrapolation,” by predicting uncertainties in new environments or conditions of interest. Extrapolation of large-scale models would address both untested parts of the parameter space and higher levels of system complexity in the validation hierarchy.

The explicit formulas presented in ➤ Sect. 6 are based on the linearized relationship between responses and parameters that customarily underlies the “propagation of moments” method, without explicitly considering nonlinearities and modeling errors. Nevertheless, neither of these limitations is as severe as it may appear at first glance, since: (1) modeling errors

can be treated in a manner similar to parameter uncertainties, as shown in Cacuci et al. (2005) and Cacuci (2003), by including the discretization intervals in the vector of model parameters; and (2) nonlinear relations between computed responses and model parameters can be treated iteratively, and hence by considering (224), all of the major results derived explicitly in ➤ Sects. 3 and ➤ 4, as the first step in an iterative procedure, which starts with the known nominal values of the quantities involved. The subsequent step of such an iterative procedure would be to use the formulas for the best-estimate mean values and covariances for the parameters and responses obtained (➤ Sect. 6.2) as the “prior information,” and compute the new (“second-generation”) best-estimate quantities by using once again the formulas (➤ Sect. 6.2). This iterative procedure would be repeated until the best-estimated values would not change any longer, thereby indicating convergence of the nonlinear iterative procedure.

Ongoing research is currently devoted to the explicit treatment of modeling errors, and to extending the results (➤ Sect. 6.2) by including not only the sensitivities (i.e., first-order information) but also the Hessians (i.e., second-order information) of the responses. Additional work is also ongoing to remove the current restriction to Gaussian distributions. Actually, the de-facto limitation to Gaussian distribution is characteristic of all of the state-of-the-art procedures for data assimilation and model calibration, as evidenced by the scientific literature published thus far. Removing these limitations would contribute significantly to understanding the validation of coupled nonlinear multi-physics models (e.g., of two or more physical phenomena that were not coupled in the initial validation database), particularly the accompanying increase of uncertainty. Developing predictive experimentally validated “best-estimate” numerical models is particularly important for designing new technologies and facilities based on novel processes, while striving to avoid, as much as possible, the costly and lengthy procedures of building representative mock-up experiments, which might confirm – but would not necessarily explain – the predictions of simulation tools.

It may be argued that the costs of “validation, verification, and model calibration through data assimilation” activities could exceed their value added. It is conceivable that such an argument could be correct under certain circumstances. However, the costs of “validation, verification, and model calibration through data assimilation” must be weighed against the costs of incorrect or improper decisions based on possibly faulty computational modeling and simulation. Analogous to probabilistic risk assessment activities, *risk* is typically defined as the product of the probability of the occurrence of the event and the consequence of the event. If erroneous conclusions based on modeling and simulations are made on high-consequence events, decision makers could place their constituency at extreme risk. This is especially true for systems that cannot be tested. For such systems, the only path to progress is to improve drastically the confidence and understanding of computational simulations, while continually relaxing their limitations and enlarging their validation domains.

Abstract: The CEA (Commissariat à l’Energie Atomique) is strongly involved in R&D research programs concerning the use of nuclear energy as a clean and reliable source of energy and consequently is working on the present and future generations of reactors on various topics such as ageing plant management, optimisation of the plutonium stockpile, waste management and innovative systems exploration. Core physics studies are an essential part of this comprehensive R&D effort. In particular, the Zero Power Reactors (ZPR) of CEA: EOLE, MINERVE and MASURCA play an important role in the validation of neutron physics calculation tools (codes and nuclear data).

Most recent programs notably contributed to:

- Obtain a very large and accurate experimental database for nuclides arising in plutonium and waste management (heavy nuclides and long lived fission products).
- Explore long-lived nuclides transmutation.
- Support the present French PWR fleet and the future reactors such as EPR.
- Explore innovative systems and new concepts in terms of new materials and fuels (ABWR, new MTR such as the Jules Horowitz Reactor under construction in Cadarache).
- Improve the physics of hybrid systems, involving a sub-critical reactor coupled with an external accelerator (ADS). A vast majority of these programs are carried out within the frame of international collaboration.

The Zero Power Reactors are also essential tools in the activities of teaching various topics related to experimental reactor physics. In particular, practical work on the operation and control of reactors and the associated methods of experimentation is done by the students enrolled in the “Génie Atomique” French nuclear engineering school.

The experimental programs defined in the EOLE, MINERVE and MASURCA facilities aim at improving the calculation routes by reducing the uncertainties of the experimental databases. They also provide accurate data on innovative systems in terms of new materials (moderating and decoupling materials) and new concepts (ADS, ABWR, GEN IV) involving new fuels, absorbers and coolant materials.

After a description of the previous experimental programs, an overview of the future experimentation is given in this chapter.

1 The Contribution of CEA Critical Mock-Ups in Nuclear Reactor Simulation

From the beginning of history of the nuclear reactor, the example of Zoé, the first French reactor, demonstrates that there is no development of nuclear concepts and techniques without an experimental portion conducted on critical mock-ups. Of course, neutronics relies on equations that are perfectly representative of the phenomena. However, the amplitude of energy fields at stake, the diversity of materials and their characteristics, and the complexity of assembly geometry means that it involves qualifying all physical data and calculation models with precision, making experimentation on such mock-ups a necessity. It will remain in the future within the context of developing digital simulation to enable adjustments and the qualification of simulation methods and tools.

CEA contributes to the study of reactor physics by designing and performing integral experiments for the qualification of neutron calculation forms, protection (gamma and neutron

attenuation in materials), and basic nuclear data on three critical mock-ups at Cadarache: EOLE (PWR and BWR spectra), MINERVE (all types of spectra), and MASURCA (“fast” and accelerator-driven lattice (ADS) spectra).

These critical mock-ups are reactors which use very low powers. Their neutronic behaviors can be directly extrapolated with physical phenomena encountered in power reactors (to a *close representativity factor*). In EOLE, the experiments conducted have always been designed in such a way that the C/E (calculation/experimentation) deviation highlighted is directly the calculation error that would be obtained in the industrial application (representativity factor mock-up $r = 1$ as it uses the same fuel and the same geometry as PWR and BWR assemblies).

These mock-ups are very flexible, adaptable, easy to access and easy to instrument while still being reliable.

Designing integral experiments consists in using a sequence of sensitivity calculations and uncertainty calculation models and should enable verification of the adequacy of the experiment with the expressed qualification requirement.

Conducting neutronic experimental programs is based on determining and measuring main parameters or phenomena of interest to qualify calculation tools and nuclear data “libraries.” Two types of main integral experiments can be identified: fundamental type aimed at qualifying basic nuclear data by measuring parameters which are themselves fundamental such as k_{eff} , spectral indexes, integral cross sections, ^{238}U conversion rates, temperature coefficient, or β_{eff} and mock-up type aimed at qualifying calculation methods through project parameters such as reaction rate distributions, soluble boron efficiency, efficiency of absorber rod clusters, or drainage coefficients.

Determining these parameters relies on the use of numerous and different experimental techniques that can be classified into three main families depending on whether the measurements are used to determine.

- Measuring techniques to determine the “absolute” (reactivity scale) or “relative” reactivity (difference between two levels of reactivity).
- Measuring techniques to determine the distribution of “in core” or “postirradiation” reaction and flux rates.
- Measuring techniques for gamma or neutron dose determination.

Experimental parameter values must be accompanied by controlled uncertainty values. Therefore, for a given parameter, the simultaneous use of several measuring techniques allows the systematic uncertainty term to be lowered. Conducting several series of measurements with a single experimental technique allows this aim to be achieved.

Within the framework of simulation development and with the aim to improve calculation scheme predictions by improving mathematic models and databases used in neutron forms, this naturally leads to the development of new measurement methods and related acquisition channels or improvements of existing experimental techniques.

Thus, determining experimental uncertainty is associated with the implementation, maintenance, and evolution of these techniques, as well as with the development of new measuring techniques. For example, the recent development of a measuring channel of the capture cross-section of U^{238} directly on fuel rod during the MISTRAL program in EOLE and that of a dynamic reactivity measuring channel using a pulsated neutron generator can be quoted.

The improvement of these methods also requires advanced instrumentation expertise. To closely measure local parameters of cores with more precision, very small-sized fission chamber

type neutron flux detectors had to be developed associated with an acquisition electronic system and signal processing to allow satisfactory analysis of measurements.

2 Description of the EOLE Mock-Up

The EOLE experimental reactor (➤ [Fig. 1](#)), with very low power, is a support structure comprising a reactor block offering biological shielding for operation with a flux level up to $10^9 \text{ n cm}^{-2} \text{ s}^{-1}$ in the core. The regulatory limit is currently 100 W whereas in the building order the limit was at 10 kW.

In this structure, an aluminum (AG3) tank of approximately 2.3 m in diameter and 3 m high was built to receive 12 tons of heavy water from the first experimental programs (➤ [Fig. 2](#)).

■ Figure 1
View of reactor block

■ Figure 2
View of the EOLE tank from above

Figure 3
View of EPICURE tank

In the center of this tank (called EOLE), there is another smaller tank (EPICURE tank: $h = 1,200$ mm, inner diameter = 984 mm, outside diameter = 992 mm). A shell inside this tank ($h = 1,122$ mm, inner diameter = 944 mm, outside diameter = 956 mm) allows it to receive any type of water reactor lattice thanks to a set of interchangeable grids (► [Fig. 3](#)).

For the requirements of the FUBILA program, this internal tank was replaced by another slightly larger one (FUBILA tank: $h = 1,194$ mm, inner diameter = 1,188 mm, outside diameter = 1,200 mm). The FUBILA shell inside this tank has the following dimensions: $h = 1,093$ mm, inner diameter = 1,148 mm, outside diameter = 1,160 mm.

Four safety rods, attached to hoists above the shell, for which the structure (plate or rods), position, and composition, depending on the cores studied, allow the reactivity to be controlled at any times. Its rods drop very quickly through a launcher and gravity.

Likewise, a pilot rod for which the structure, position, and composition can be chosen allows divergence to be carried out and power to be stabilized between 0 and 100 W (maximum power authorized). This pilot rod has a reactivity weight lower than $\beta/2$.

Fuel rods are identical in height (80 cm fissile height) to those of lattices used in power reactors (uranium oxide or mixed uranium and plutonium oxide).

Several types of fuel (MOX, PWR, and BWR type UO_2) have been used in the facility and some of them are still available for future programs:

225	MOX EPICURE 8.7% rods
1,604	MOX EPICURE 7% rods
202	MOX EPICURE 4.3% rods
23	MOX BASALA 3% rods
20	MOX FUBILA 3% rods
36	MOX FUBILA 5% rods
120	MOX FUBILA 8% rods
264	MOX FUBILA 11.5% rods
1,600	UO_2 EPICURE 3.7% rods

As an example, the core loaded with the most MOX fuel (MISTRAL-2) contained approximately 44 kg of Pu.

However, it should be noted, that the facility is unable to use and store irradiated fuel that limits EOLE to lattice characterizations at “Zero time,” without the ability to qualify changing codes.

Numerous absorber materials, burnable or structure poisons (natural and enriched B_4C , AIC, Hf, $UO_2-Gd_2O_3$, $UO_2-Er_2O_3$, pyrex, Zy-2, steel, etc.) can be used.

In 1995, a thermostation was set up with water systems enabling filling, drainage, and the introduction of boron in the moderator able to get the moderator's temperature to be selected from 5 to 80°C with $\pm 0.1^\circ C$ precision (➤ Fig. 4).

In 1997, the installation of a small chemical laboratory enabling precise measurement of the soluble boron concentration of the moderator can also be noted (➤ Fig. 5).

In 1990, the reactor's instrumentation and control system was entirely refurbished with, in particular, neutron signal digital processing, the use of programable controllers, and the visual display of reactor status (➤ Fig. 6). In 2003, neutron control racks and the supervisor were updated (➤ Fig. 7).

Searching for the critical status of the reactor is carried out by the rise of the moderator solution (borated or not) in the reactor tank, then, when the moderator solution circulates in the thermo-control system at the desired temperature (by overflow between the tank and the shell) by the gradual rise of the control rods.

The reactor must be slightly subcritical with the four control rods in raised position, pilot rod fully inserted in the core and slightly supercritical with the pilot rod in raised position

■ Figure 4
View of the thermostation

■ Figure 5
View of the small chemistry laboratory

■ Figure 6
View of the control room (1990)

(there are therefore no longer any absorbers in the core). Criticality is sought with the pilot rod partially inserted in the core.

Core reactivity is adjusted through iteration on one of the following two parameters:

- Moderator concentration in soluble boron (light water)
- The fuel mass by adding or removing some peripheral fuel rods

These two parameters are called *critical parameters*.

3 Experimental Programs on the EOLE Mock-Up

The Building Order for EOLE dated 23 June 1965 was signed by Prime Minister Georges POMPIDOU and the Secretary of State for the first Minister responsible for Scientific, Atomic, and Space Research, Yvon BOURGES. The EOLE nuclear reactor, which was built to study CELESTIN lattices, replaces the AQUILON reactor (D_2O natural and enriched uranium at Saclay 1956) and constitutes a flexible critical experiment for the physics of cores and has a D_2O reference thermo-column. The maximum operating power was 10 kW.

After 2 years of work (1964–1965), the first divergence took place on 2 December 1965.

1965: Natural uranium and heavy water Thermo-Column calibration with respect to Aquilon reactor.

1966: Study of CELESTIN lattices notably with a plutonium and heavy water lattice.

1968: The FOEHN experiment was a critical mock-up of the RHF high flux reactor at the Laüe-Langevin Institute in Grenoble.

1969: Validation of calculation codes for EL4 type lattices.

1970: Lattice EL3 experiment with enriched U annubis tubular fuel (93%).

1970: Marks the end of the use of heavy water in EOLE.

1971: Critical experiment for a thermoelectronic direct conversion reactor, with ceramic fuel – molybdenum enriched uranium metal and tungsten electron conductor.

1972: Critical mock-up of safety test reactors with the CABRIOLE program for CABRI, the PHEBEE program for PHEBUS and SCARABEE.

1978: The CRISTO I program for the study of the criticality of pressurized water reactor large pitch fuel storages. An additional CRISTO-Mist configuration simulated the density of optimum hydrogen (fire or mist/smoke lance in dry storage) through expanded polystyrene blocks in which fuel rods were inserted.

1979: The CREOLE program for the study of temperature coefficients for UOX and MOX fuels. 200 MOX rods were placed in a loop (temperature at approximately 300°C pressurized

at 120 bars. This experiment allowed, for example, a precise form of the ^{235}U η factor to be obtained).

1980: The CRISTO II program for the study of PWR assembly large pitch fuel compact storages for pressurized water reactors.

1982: The CAMELEON program was dedicated notably to the qualification of calculation schemes for neutron absorbers (hafnium, boron, gadolinium with different supports, co-milled or grain) in UO_2 PWR type cores.

1985: The ERASME program studied closed MOX lattices, under-moderated for cores for ^{238}U - ^{239}Pu convertor.

Since 1989, EOLE has been mainly dedicated to plutonium recycling studies in light water reactors (PWR and BWR).

3.1 The EPICURE Program

The EPICURE program (between 1989 and 1994) was jointly agreed upon in 1988 by the three partners EDF, FRAMATOME, and CEA and was to examine uncertain margins related to neutron quantities associated in PWR with plutonium recycling and propose actions needed for their reduction in such a way as to not penalize the operation of plant units concerned, by ensuring the required level of safety.

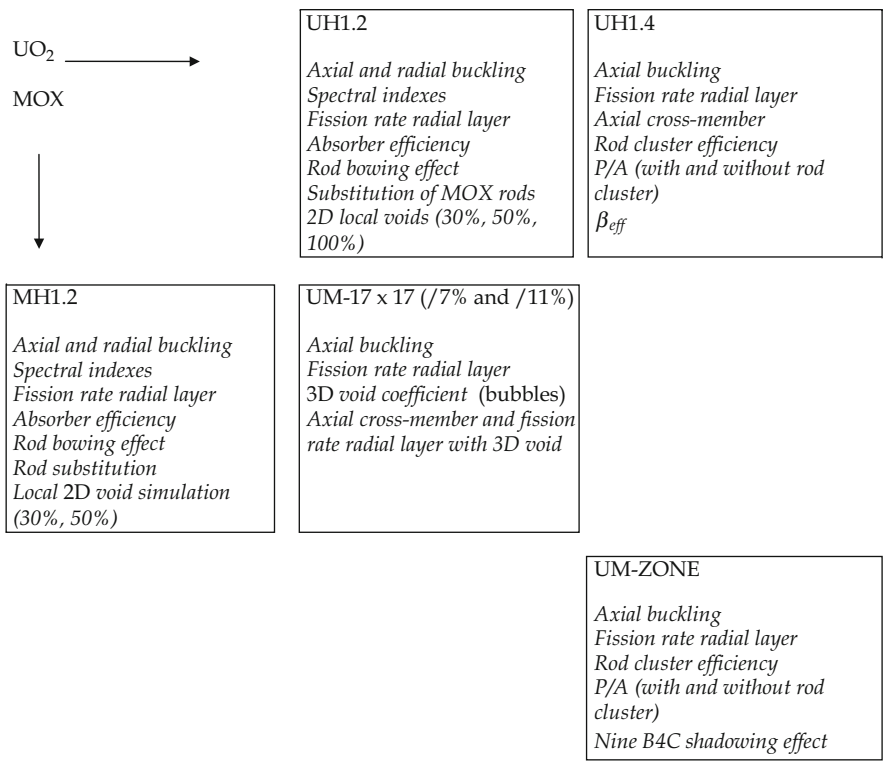

It also had the objective of qualifying calculation schemes of PWR cores loaded to 30% of MOX assemblies (➡ [Fig. 8](#)).

EPICURE therefore enabled reduction of the calculation uncertainty of the multiplication factor of PWR lattices by a factor of 2. Furthermore, it returned the precision of MOX lattice parameters to the level of that of UO_2 lattices.

Particular attention had to be paid to problems linked to the interface between MOX and UO_2 assemblies. A statistical analysis allowed a distribution map to be created for fission rates with an experimental uncertainty of $\pm 0.6\%$ (at 1σ) for UO_2 rods and $\pm 0.9\%$ (at 1σ) for main assembly MOX rods (the uncertainties for existing MOX experiments are approximately $\pm 1.5\%$). Uncertainty on the power peak was able to be decreased by more than half to arrive at 1%.

The diagram below summarizes the configurations and different measurements studied: The EPICURE program also enabled:

- Through its representativity, qualification of the MOX/ UO_2 interface calculation and zoning, as well as qualification of the P/A factor (assembly average power divided by the activity of the fission chamber placed in the center of the assembly)
- Qualification of calculations of various types of absorber rods, as well as the obtaining of an experimental basis for the validation of absorbers in UO_2 and MOX PWR assemblies
- Power distributions and reactivity effects in the case of local drainage as well as for rod bowing effects to be obtained
- Qualification of the APOLLO-2 code and basic data, notably the CEA93 library. Furthermore, interpretation of the PWR type configuration recycling plutonium, enabled a reference calculation scheme based on the APOLLO-2 Sn 2D module to be developed.

■ Figure 8
View of the EPICURE MH1.2 configuration

3.2 The MISTRAL Program

The MISTRAL program (between 1995 and 2000) in collaboration with the Japanese organization “NUPEC” (Japan) and the French industrial partners EDF and FRAMATOME, accompanied Japanese and French studies on MOX 100% loaded cores with increases of the moderating ratio $H/HM = 4-6$ in four different configurations including one mock-up type.

The experimental program was centered around four experimental cores in which the majority of neutronic parameters of Advanced water reactors loaded at MOX-100% were measured, and for which the moderating ratio is increased with respect to that of standard PWR currently in operation in France. The cores were the following:

- MISTRAL-1: This involved a core with a moderating ratio of approximately 1.8 (H/HM ratio ~ 5.0) loaded with UO_2 rods with 3.7% ^{235}U . This core was used as a reference for cores at 100% MOX (► [Fig. 9](#)).
- MISTRAL-2: This involved a core with a moderating ratio of approximately 1.8 (H/HM ratio ~ 5.0) loaded with MOX rods at 7%.
- MISTRAL-3: This involved a core with a moderating ratio of approximately 2.2 (H/HM ratio ~ 6.0) loaded with MOX rods at 7%.
- MISTRAL-4: This involved a mock-up core in which a certain number of advanced PWR assemblies were simulated. The lattice pitch was set at 1.32 cm so as to increase the moderating ratio with respect to a standard PWR and thus approach the design of advanced PWRs able to recycle 100% of MOX fuel. The moderating ratio for this core was approximately 2.1 (volume) (► [Fig. 10](#)).

The MISTRAL program allowed experimental results, never conducted so far, to be obtained. Their analysis through calculation allowed trends on nuclear data libraries to be obtained and calculations to be modeled.

The implementation and improvement of the measuring technique proposed by Nakajima (JAERI) helped obtain the conversion rate modified in MOX and UO_2 rods in fundamental mode at better than $\pm 2\%$. The ^{238}U capture rate shows a slight overestimation in JEF2.2, which seems to increase with the moderating ratio.

■ **Figure 9**
View of the MISTRAL-1 configuration

■ Figure 10
View of the MISTRAL-4 configuration

The measurement of the bucking parameter in the MISTRAL allowed it to be confirmed that the UO_2 multiplication factor was overestimated (problem with the ^{235}U capture section in the resonance range in JEF2.2) and also overestimated in the MOX.

The installation of a thermoregulation lattice on the EOLE reactor enabled measurement of the isotherm temperature coefficient between 10 and 80°C in the MOX and UO_2 lattices with very good precision. The measured temperature coefficient allowed it to be concluded that in UO_2 , the calculation perfectly reproduces the measurement and the entire temperature range as well as the $10\text{--}40^\circ\text{C}$ range for MOX. However, between 40 and 80°C , underestimation is observed in the MOX lattices.

The differential worth of the soluble boron was measured around the critical value at $\pm 5\%$. The full worth was also measured in a critical CB Boron concentration at critical $\text{CB} + 600$ ppm. Measurements show that this worth is almost linear with the quantity of boron.

The fraction of delayed neutrons was measured with the neutron noise method at better than $\pm 3\%$ in the MOX and UO_2 lattices. The fraction of delayed neutrons is well reproduced in the MOX by APOLLO-2 and the CEA93 library with a tendency for slight overestimation in UOX.

MISTRAL enabled distinct improvement of precision on central absorber rod reactivity effects ($\text{UO}_2\text{--Gd}_2\text{O}_3$, AIC, natural B_4C and enriched B_4C representative of PWR) as well as related fission rate distributions with respect to measurements carried out in EPICURE.

In the same respect, the MISTRAL-1 lattice was taken advantage of to conduct a short program (MIRTE) to study the negative reactivity of erbium within the wider scope of the EROINE program.

Due to a relatively large lattice pitch, the MISTRAL-3 core enabled simulation of a zone drained at 100% in a 100% MOX lattice to be carried out. The reactivity effects and distribution of radial and axial fission were carried out with very high precision. The drainage effects

in MISTRAL-3 are reproduced very well by APOLLO-2 (reactivity effect and power distributions). As for APOLLO-2, calculations showed some deficiencies linked to the lack of aluminum self-shielding and weaknesses linked to the implementation of condensation/homogenization techniques.

The MISTRAL-4 core allowed for simulation of an advanced PWR with increased moderation and loading to 100% MOX. In particular, a systematic study of rod assemblies representative of 24 absorbers was undertaken (natural hafnium, Ag-In-Cd, natural B_4C and enriched B_4C rods). Thus, it was possible to assess their relative and absolute worth as well as related fission rate distributions.

The enriched B_4C 24 rod cluster (90% ^{10}B and 70% theoretical density) was studied both in a 100% MOX assembly and in a UO_2 assembly. This experiment allowed comparison of worths and related power distribution map.

3.3 The BASALA Program

The international BASALA program, conducted between 2000 and 2002 in collaboration with the Japanese organization NUPEC, and the COGEMA was accompanied by Japanese studies on cores loaded at 100% MOX in boiling water reactors (9×9 rod assemblies). Two cores in particular were studied:

- The BASALA H core representative of a 100% MOX advanced boiling water reactors (ABWRs) core in hot operating conditions (190°C, 75 bars, 42% average void fraction).
- The BASALA C core representative of a 100% MOX cold ABWR core (0% void fraction and $T = 20^\circ C$).

Each core was the subject of several configurations allowing neutron parameters representative of a nuclear reactor to be studied, for 100% MOX BWR assemblies:

- In reference conditions
- In the presence of burnable poisons
- In conditions simulating strong drainage rates
- In presence of absorber control cross (B_4C and/or Hf) with fuel substitutions

The objectives in terms of target uncertainties were reached and calculation results also generally reproduce the experiment well. Thus, it can be noted that:

- BASALA cores were perfectly characterized in terms of reactivity: reactivity effects of heterogeneities were assessed at better than 6% (1σ) and Monte Carlo calculations reproduce these various effects very well.
- More than 1,200 rods were the subject of gamma spectrometry measurements with an experimental uncertainty of $\pm 1.0\%$ to $\pm 1.7\%$ (1σ) both in reference cores and disturbed cores: Monte Carlo codes reproduce power distribution maps measured at better than $\pm 1.4\%$.
- The reactivity effect of metal Hf and natural B_4C control crosses was measured in the BASALA-C configuration and are of the same order of magnitude (therefore in cold conditions).
- The temperature coefficient in BASALA-C without absorbers is positive till 30°C.

■ Figure 11
View of the BASALA-H/REF configuration

■ Figure 12
View of the BASALA-C/REF configuration

- The full reactivity effect of soluble boron is almost linear between 0 and 600 ppm in the reference BASALA core (➤ [Figs. 11](#) and ➤ [12](#)).

3.4 The ADAPh Program

In 2004, from January to April, the ADAPh program (*Amélioration des Données de bAse Photonique* – Photonics Basic Data Improvement) was used to support qualification of the HORUS-3D-P tool intended to calculate photon heating of Jules Horowitz's Reactor systems. It will be used as a support element during presentation of the Preliminary Safety Report (PSR) closer to 2008.

However above all, the objective of the ADAPh program was the qualification of the thermoluminescence technique for the future AMMON experimental program. The targeted objective, which is quite ambitious, is to ensure approximately 15% (2σ) precision on heating calculations. Currently, precision linked to basic data is estimated at 30% (2σ). Precisions obtained on gamma dose rates in measured positions are approximately 7% (at 1σ). The techniques used are explained in the chapter on gamma heating measurements.

3.5 The FUBILA Program

The main objective of the FUBILA experimental program is an experimental database to accompany the validation of codes related to the design of high combustion rate ABWRs, recycling plutonium. Its main characteristic is the increased representativity allowed by the implementation of BWR geometry rods (larger diameter than PWR) and higher plutonium contents.

The FUBILA program is dedicated to the study of 9×9 and 10×10 100% MOX assemblies with high combustion rates and increasing void fractions: 0, 40, and 70%. The void is modeled through the addition of aluminum cylinders inserted between fuel rods or through an AG3 solid block in which rods are inserted (● Fig. 13).

■ Figure 13

Central patterns of REF (0% void – on the left) and 10×10 (40% void – on the right) experimental zones: FUBILA MOX-3%, FUBILA MOX-5%, FUBILA MOX-8.5%, FUBILA MOX-11.5%, and AG3 rods to simulate the housing for advanced boiling water reactor (ABWRs)

■ Figure 14
FUBILA/REF core

This program, which was centered around eight main cores, was carried out in EOLE between January 2005 and September 2006 (► [Fig. 14](#)).

3.6 The FLUOLE Program

3.6.1 Reason for the Program

In current PWRs, peripheral assemblies comprise an approximately 2-cm thick steel baffle located between the fuel rods and the barrel (a relatively thick moderator zone is also present between the baffle and the barrel).

If a water reflector slows down the neutrons directly through elastic scattering on hydrogen atoms, the baffle's steel behaves more like a spectrum adaptation zone by slowing down fast neutrons into epithermal neutrons, through inelastic scattering on the steel's constituents. These inelastic sections are not known very well and the energy field concerned has been studied little in water reactors as main reaction rates are produced in the thermal (fissions) and epithermal (captures in resonances) field.

Thus, the calculation of these inelastic slowing phenomena and consequently the calculation of the reflector gain is marred by high uncertainties for which CEA does not have experimental results in representative situations in order to qualify both the calculation tools and basic data libraries.

The fluence and damages suffered by the reactor tank are limiting factors for the service life of nuclear power plants and they should be evaluated. In this perspective, there are a certain number of capsules containing specific irradiated materials in a zone near the PWR tank (depending on the type of bearing). The analysis of detectors arranged in these capsules allows the fluence received by the capsule to be determined using neutronic calculation results; then, the calculation allows fluences and damages on the tank to be estimated.

As indicated above, several types of materials are located between the core assemblies and the reactor tank. These include the steel baffle (22.2-mm thick), a water area, the reactor barrel (approximately 5 cm), another water area, the thermal shield, a third water area, and finally the detector holder, which contains capsules in a water area, then the tank.

Furthermore, the thermal shield and the detector holder are not present on the entire periphery of the core and the peripheral part of the core is not cylinder-shaped. Consequently, the tank does not undergo the same fluence everywhere and capsules are not necessarily representative of the whole.

Analysis through the calculation of capsule detector reaction rates indicates deviations ranging between 10 and 15% depending on the type of reaction in question. Consequently, the fluence undergone by the tank is marred by a relatively high bias.

- The source of neutrons in the fuel itself (distribution, fission spectrum)
- The cross-sections of the various materials located between the fuel and the tank
- The cross-sections of detectors
- The model used in the calculation

In order to determine the contribution of each parameter to the bias and be able to draw leads to reduce such bias more accurately, the decision was made to define a targeted experimental program implementing several “steel/water” sandwiches located at various distances from the core and to measure the reaction rates provided by the detectors at activation covering the same energy field as those used in the irradiation capsules.

This FLUOLE program provides significant information for the validation of the TRIPOLI 4 (Monte Carlo Transport Code) scheme for the tank fluence of PWR 1,300s, for which there is currently no experimental data, as the water-steel distributions are different than those for PWR 900s. This scheme should be in use when the Safety Authorities assess files which EDF (French Nuclear Operator) will present to obtain the authorization to extend the service life of PWR 1,300s beyond 40 years. At this time EDF will no longer have any (or very little) margins on fluences with respect to those of design. The scheme must therefore be perfectly validated in terms of centered values hence the potential determination of bias by comparison of calculations/measurements and uncertainties.

3.6.2 Characteristics of the FLUOLE Program

One of the characteristics of this experiment is the possibility of simulating several azimuths around the EOLE core and of obtaining precise measurements for different neutron energy levels through specific instrumentation depending on water and steel thicknesses. They will also be conducted through fission chambers and through dosimetry per activation. The latter is adapted to obtain maximum information on the neutron spectrum and its distortion in water-steel leafing.

Collaboration with the CEA laboratories specialized in measuring very low activities will allow results obtained through dosimetry in these high attenuation neutron fields to be compiled. In addition, measurements taken through gamma spectrometry on EOLE rods will allow precise characterization of sources for the calculation.

It led to introduce into EOLE a 29×29 cell PWR type square core containing 3.7% ^{235}U enriched UO_2 fuel rods with Zy-4 cladding and placed under AG3 double-cladding in order to

■ **Figure 15**
Core structures during mounting and adjustment

obtain a moderating ratio representative of PWRs on the spot (identically to EPICURE where the over-cladding was 0.5-mm thick).

Four control/safety rods are placed in the corners of this square and a pilot rod is required to control the reactivity around the criticality. This is obtained by boric acid dilution in the moderator.

The water-steel leafing encountered in PWR between the core and the tank (baffle, barrel, and thermal shield) is simulated by a 22.2-mm thick stainless steel baffle (identical to that of PWRs) one part in stainless steel with a 1/2 cylinder shape and another part in stainless steel with a 1/2 cylinder shape with a different radius.

A schematic diagram of this configuration is shown in ➤ [Fig. 15](#).

Measurements were specifically dedicated to measure the flux using activation detectors such as ^{115}In (fast flux > 1.3 MeV), ^{64}Zn (fast flux > 2.8 MeV), ^{27}Al (fast flux > 7.3 MeV), ^{197}Au , and ^{55}Mn (thermal and epithermal flux). Reaction rates were carried out on representative cross-members (for example the two diagonals) in all the core materials (fuel, reflector, baffle, barrel, and thermal shield). Miniature fission chambers enabling access to the fission rate of specific isotopes (for example, ^{237}Np , fast flux representative of DPAs; ^{235}U , thermal flux) were also implemented.

The FLUOLE program took place on EOLE between October 2006 and June 2007 (➤ [Fig. 16](#)).

3.7 The PERLE Program

3.7.1 Reason for the Program

Currently, all experimental programs conducted at CEA, and particularly at EOLE, have only implemented cores with moderator at their periphery (borated water reflector or not).

Current design studies for the EPR reactor use a thick stainless steel reflector, generally called “heavy reflector,” instead of the standard baffle and the water located between the baffle and barrel, in order to limit the fluence suffered by the tank and to improve the reflection of fast neutrons.

■ **Figure 16**
FLUOLE Upper grid with core mini-grid mounted

This concept emphasizes even more the inelastic diffusion phenomena mentioned above and leads to quite different reflector gains than those obtained with a water moderator. A targeted experimental study will help obtain necessary information on reflector gains and neutron attenuation in the heavy baffle. Effects on the power distribution map (switches) should also be assessed.

In addition to the “neutronic” effects, all the materials located between the assemblies of the core and the tank undergo a very high rate of irradiation through gamma rays, which contributes notably to their heating through energy deposit. This phenomenon is predominant for heavy reflectors for which there are currently water channels for cooling. The quantity, dimension, and location of cooling channels are strongly tied to the amount of γ radiation deposited. An in situ measurement is required to validate the design calculations.

The PERLE program (*Programme d’Etude de Réflecteur Lourds dans Eole* – Heavy Reflector in Eole Study Program) is intended for the qualification of calculation tools used for the EPR reactor and specifically to assess the calculation errors linked to the presence of the steel reflector around a PWR rod zone.

3.7.2 PERLE Program Characteristics

In order to maintain certain consistency with FLUOLE, it was considered of interest to define the common lattice (pitch, size of the over-cladding). Thus, it will involve introducing into EOLE a 27×27 cell (instead of 29×29 in the FLUOLE program) PWR type square core containing 3.7% ^{235}U enriched UO_2 fuel rods with Zy-4 cladding and placed under AG3 double-cladding in order to obtain a moderating ratio representative of PWRs on the spot.

Likewise, the four control/safety rods will be placed in the corners of this square and a pilot rod will be required to control the reactivity around the criticality. This will be obtained by diluting boric acid in the moderator.

A schematic diagram of this configuration is shown in ► [Fig. 17](#).

■ **Figure 17**
Schematic diagram of the PERLE configuration

The experimental program took place in two phases of approximately 5 and 3 months during which the physics phenomena linked to the presence of the steel heavy reflector is investigated in detail (determining the reflector gain, neutron propagation within the reflector, gamma heating, etc.) with the aim of reducing uncertainties on cross-sections of steel constituents. The program is structured around two different core configurations.

The Homogeneous Configuration

The PWR regular lattice core with homogeneous reflector constitutes a first step in generating an experimental database related to the qualification of the steel reflector concept. This core will enable:

- Qualification of the reflector gain calculation
- Qualification of the core/reflector interface calculation
- Qualification of the neutron flux with intermediary energies in the reflector
- Assessment of the induced gamma heating in the steel
- Reduction of uncertainties on nuclear data and quantification through a TRIPOLI-4 standard calculation
- The feed-back return on the JEFF-3.1 data library assessment

Configuration with “EPR Type Reflector”

The final step, based on the parametric approach that is used for years in designing a full qualification program, comes after an intermediary step where, *a minima*, local heterogeneities of the heavy reflector must be reproduced in a representative manner, which can be easily done. For this reason, the reflector was redesigned in order to take into account the presence of water channels on one side of the core. Thirty-five holes with 13-mm diameters (● [Fig. 17](#)) are drilled into the block and plugged with steel mandrels to ensure sealing and homogeneity of the matter during the “homogeneous steel reflector” phase. When switching onto the configuration with

■ Figure 18

View of the block with water channels, plugged by steel mandrels (homogeneous configuration)

water channels, these mandrels are removed allowing the water to penetrate into the heavy baffle (► Fig. 18).

The scientific interest of this type of configuration is different from the configuration with a homogeneous reflector. Here it involves directly measuring the neutronics parameters impacted by the presence of said water channels, which locally generate over-moderation that is unfavorable to the reflector gain (increased thermalization of neutrons in the steel followed by absorption).

Here, the predominant measurements, other than the critical size, which will give macroscopic information on the reactivity effect of water channels compared to the homogeneous case, will be the neutron flux and gamma heating cross-members coupled with measurements by different threshold fission chambers.

The effects of water channels on the critical size and also on the local distribution of fine rod/rod power are significant. The last design calculations carried out using TRIPOLI-4, showed the following effects:

- The effect on the k_{eff} is 300 pcm, measurable with excellent accuracy through the adjustment of the configuration's boron concentration. This effect is equal to a reduction of the boron concentration by approximately 27 ppm, measured with 0.1 ppm (0.5%) precision.
- The effect of flux distribution in the heavy baffle at the mid-height plane of the core is clearly visible in intermediary regions ($E_n > 100$ keV) and in the thermal field ($E_n < 1$ eV). The disturbance generated is approximately several tens of percents in the zones where the water holes are concentrated, much higher than measurement precisions by fission chambers (1%) or by dosimeters (2–3%)
- The effect on flux distribution in the first rows of fuel is between 5% for the first row and approximately 2% at the fifth row, much higher than the precision of measurements by γ -scanning (1%).

In addition to the points previously mentioned for the configuration with homogeneous reflector, this configuration will enable:

- Qualification of local heterogeneity effects in the calculation of the reflector gain, in terms of reactivity but also in terms of neutron and photon spectrum disturbance, as shown in the previous figures
- Determination of the reflector's gamma heating with channels
- Calibration of a reference deterministic model for this simplified case with water channels
- Recommend new industrial calculation schemes and methods and deduction of methodological biases

The PERLE program took place between July 2007 and June 2008.

3.8 The AMMON Program and the Jules Horowitz Reactor

EOLE provides experimental qualification information as part of the design of the Jules Horowitz reactor (JHR) and the development of the *HORUS3D* form (► Fig. 19).

In particular, qualification of the UMoAl type fuel intended for the JHR led to:

- A test program conducted on MINERVE in 2003 to specify the UMoAl basic neutron data (reactivity, reaction rate): *VALMONT* program.
- A more in-depth program to qualify all the neutronic characteristics of the JHR core, on EOLE: *AMMON* program. This last program on EOLE should provide a set of calculation tools needed to design the JHR.

■ Figure 19
Radial cross-section of the Jules Horowitz reactor (JHR) core

■ Figure 20

JHR definition and development process procedure, associated with safety and qualification deadlines

Qualification of the HORUS3D neutronic form must accompany the requirements related to the basic design of JHR, separated into two phases: definition and development (► Fig. 20).

The elementary qualification experimental requirements for the preliminary safety report (PRSR) are covered by the following experimental programs: VALMONT, ADAPh, and IRIS- γ . Specific qualification elements are required to draft the Preliminary Safety Report (PSR).

The measurements for this program first aim at demonstrating the control of significant safety aspects. Therefore, the experimental objectives involve:

- The reactivity of a JHR assembly
- The fine distribution of power in the assembly
- The reactivity effect of absorbers (Hf control rod, borated stiffeners)
- The effect of experimental systems in reactivity and in terms of power distribution
- The reactivity effect of the Beryllium reflector and the spectrum in and near the reflector
- The void and temperature reactivity coefficients

The reference configuration for the AMMON experiment comprises seven JHR type assemblies, arranged in a hexagonal lattice inside an aluminum compartment. This housing is surrounded by a hexagonal lattice with diameter 19.2 cm, comprising approximately 415 EPICURE type UO_2 rods (3.7% mass enrichment). The pitch for this lattice is 1.40 cm in order to create a full sub-division of the hexagonal pitch for JHR assemblies and then facilitate the adaptation of the two geometries.

The schematic diagram for the reference configuration is shown in ► Fig. 21.

During the feasibility phase for the JHR project, the decision was made for the structuring option not to create a critical mock-up of the core for the JHR facility identical to the ISIS mock-up for the OSIRIS reactor. Within this framework, an operating mode for the JHR ("low power

■ **Figure 21**
Schematic diagram for AMMON configuration

mode”) was simply maintained, open on the cavity, for which the low power can be evacuated through natural convection.

The inconveniences of this mode are that it does not allow all the functions accessible on a core mock-up such as ISIS to be recreated, and that it is also used to the detriment of the operation of the powered core (reduced availability of the facility for neutron production).

The low power operating mode for JHR (“mock-up mode”) is, by definition, representative of the core + reflector geometry. It allows irradiated fuels to be measured, rods to be weighed or other objects inserted into the core to be measured. However, use of this mode has the following limitations:

- The use of soluble poisons in the primary coolant is not foreseeable; consequently, all the positions of regulating and shim rods are not accessible in the core
- At this point in studies, the possibilities of core fine instrumentation in mock-up mode have not been checked; given the presence of other internal core structures, instrumentation could be less flexible with respect to the case of a critical mock-up
- This mode is used to the detriment of the core’s power operation

The interest of EOLE for the JHR lies in the possibility of conducting full semi-analytical experiments (representative of a given pattern) in critical mock-up, in order to qualify HORUS 3D calculation forms in neutron or photon mode.

This activity is of significant interest from the start of the design phase and is worth being developed during the operation of the JHR: improvement of calculation reconstruction accuracy, ability to experimentally test or check (transparently with respect to the operating load of the JHR), local layouts which are difficult to understand through calculation alone, etc.

3.9 MOX Powder Criticality Requirements

An important meeting of experts organized by OCDE/NEA took place in April 2004. This meeting pinpointed the international lack of full critical experiments as being representative of highly under-moderated MOX powders. This problem is particularly raised for the safety-criticality file for various stations at MELOX (100% PuO₂ jars, UO₂-PuO₂ master batch at 30% Pu, final MOX and pellets up to 12.5% Pu).

In EOLE, it is possible to build homogeneous cores using enough MOX 27% Pu rods to reach the criticality of the support block (approximately 2,500 rods).

Two cores are foreseeable with moderating ratios (V_m/V_{comb}) of 0.3 (MOX master powder simulation at 30% Pu) and 0.6 (MOX 12% Pu final mixture simulation), respectively.

The following would be measured in both the configurations:

- The critical size
- The fission rate axial and radial cross-members
- The spectral indexes
- The temperature coefficient of the moderator between 10 and 80°C

These experiments would allow the uncertainty on the k_{eff} of primary and final powders to be greatly reduced through a breakdown of the various terms in the neutron balance (► [Fig. 22](#)).

3.10 Criticality at Loading

In 2001, an “incident” occurred at the Dampierre plant during the new assembly loading phase. The mistake of loading a specific assembly led to the introduction of several new

Figure 22
Schematic diagram of a POWDER configuration

assemblies in the same zone of the core and thus the approach to the criticality. This phenomenon was only detected by a small part of ex-core chambers and only at the end of the phase.

At the request of EDF, several simulation calculations for this loading phase were carried out at CEA to determine the subcriticality level of the core and the response rate of ex-core detectors depending on the time to see if there was the possibility of detecting earlier that there was a loading error.

Beyond the analysis of the Dampierre incident itself, it was observed that the responses provided by ex-core detectors of a power reactor depend greatly on the source of neutrons and therefore on the combustion rate of each core assembly and their position in relation to detectors.

Each situation is therefore very specific and consequently difficult to “model” through an experiment in EOLE. It seems that it would be much more sensible to first correctly assess the neutron source of the core for each loading step through calculation.

Next, ex-core detector responses must be modeled through calculation.

The EOLE reactor could contribute to providing a qualification basis for these models thanks to the “Multiplication of Neutron Sources” type measurement method in subcritical status, provided that:

- The subcriticality level of a core can be easily measured by the MSM method (this requires first calibrating the reactivity scale with respect to a well-known effect, for example, the pilot rod). A core containing MOX rods would be implemented in order for there to be an inherent source in the core.
- Several types of reactivity disturbances can therefore be simulated by the drop of one or several control rods, removal or addition of a sufficient number of different types of rods simulating one or several assemblies inserted or removed from the core in various areas of the core in order to vary the reactivity and/or source of neutrons. Furthermore, the soluble boron in the moderator may be used as a standard of reactivity introduced or removed from the core.

Interpretation of experimental results will allow qualification of models capable of both predicting the variation of the multiplication factor at almost constant source and at modified source as well as the detector responses in various situations. It should however be emphasized that this experiment would not be fully representative of the loading phase for a PWR.

3.11 Plutonium and High Combustion Rate Control. EPR Support

In France, plutonium control is aimed at maintaining the plutonium in the fuel's cycle and stabilizing the total inventory associated with operating the fleet over time. Plutonium mono-recycling practiced currently in the form of cores at 30% MOX fuel in PWR-900s could end up being insufficient to stabilize the inventory. Furthermore, the decision to remove irradiated MOX fuel would initially pave the way for multi-recycling in water reactors.

A need was identified for experimental programs to ensure qualification coverage of calculation tools beyond the current limit and to respond in part to new concepts.

Mock-up experiments in EOLE with highly enriched UO_2 fuel with 4.95% ^{235}U and MOX 12% fuel cores (high Pu load, multi-recycling and deteriorated Pu) could provide answers.

17×17 PWR type assembly simulations with UO_2 fuel enriched at 4.95% ^{235}U or MOX fuel enriched at 12% Pu with a 1.26 cm lattice pitch could be carried out in an EPI-CURE UH1.4 configuration type concept. The square critical contour will allow the size of the core to be increased by increasing the radial leaks. Measurements carried out using experimental techniques will be directly influenced by the key parameters of these new concepts:

- Reactivity of the core and the MOX lattice (k_{eff} , buckling).
- Fraction of delayed neutrons, life of prompt neutrons.
- Efficiency of B_4C , AIC, enriched B_4C , Hf control clusters.
- Efficiency of Pyrex, $\text{UO}_2\text{-Er}_2\text{O}_3$ burnable poisons.
- Efficiency of $\text{UO}_2\text{-Gd}_2\text{O}_3$ burnable poisons (with more Gadolinium enrichment on an enriched ^{235}U support for long campaigns).
- Soluble Boron differential worth.
- Moderator temperature coefficient (isotherm).
- 2D and 3D and total drainage void coefficient.

These programs would be associated with recent needs of utilities to launch a high burn-up (Haut Taux de Combustion, HTC) program to broaden the qualification of neutron calculation tools (60 GWj/t UO_2 and MOX parity) in order to introduce HTC fuels during future decennial inspections. The ALLIANCE program can be alluded to along with the study of EPR assembly with burn up above 60 GWj/t.

Likewise, mixed loading cores covering the 50% MOX situation planned in EPRs should probably also be built.

Naturally, it is true that EOLE can be used to support the qualification of deteriorated Pu recycling and standard geometry type assemblies (17×17 CORAIL design), comprising standard geometry rods (^{235}U enriched UOX rods at the center and MOX rods on the periphery of the assembly with a proportion of approximately 30% per assembly). From a design very close to the current standard, it is ready to be industrialized.

The short-term implementation prospects for multiple recycling of plutonium in reactors of the fleet in operation, therefore, rely on quick industrial qualification of CORAIL for introduction into reactors of the current fleet.

If CORAIL can be brought to mind for the relatively short term, in the long term the Advanced Plutonium Assembly (APA) and DUPLEX (standard geometry APA variant) concepts, which would allow the plutonium stock to be reduced if necessary, would themselves also require that related calculation schemes be qualified on a representative experimental basis. Linked to these assembly and rod concepts (The small crosses of APA-PC can notably be brought to mind), Inert Matrix fuels represent interesting solutions in terms of innovation. Several inert materials are being studied to be used as a matrix; the choice of CERMET metal matrix fuels was selected. However, the lack of uranium leads to very penalizing control parameters and notably strong deterioration of the void coefficient, the effective fraction of delayed neutrons, as well as a loss of traditional control efficiency for which we will undoubtedly be asked for precisions.

Obviously, when evoking fuel irradiated fuel or even irradiated assemblies can also be studied even if the feasibility for using this type of fuel in EOLE must currently be obtained.

3.12 Support Program for CELESTIN Reactors

Ideas for an experimental support program for CELESTIN reactors were evoked in the following topics:

- The up-grade of neutron calculation codes
- Actions to support requests of the 2002 Safety commission linked to the refurbishment of the reactors and to maintain them in operation

A need to improve knowledge on the core reactivity of reactors should allow the management of fuel assemblies to be refined through reactivity measurements on EOLE.

3.13 An Experimental Platform

CEA-Research Reactors Division has renowned expertise in the area of reactor nuclear instrumentation (flux measurement, spectral index measurement, characterization of rods after irradiation, etc.). Fundamental work is underway on the expertise of measurement methods implemented and on the management and reduction of related uncertainties:

- Measurement of fundamental neutronic parameters such as: β_{eff} – fraction of delayed neutrons, Λ – neutron life, ρ – reactivity).
- Dynamic measurement techniques (frequential methods) based on Dating systems (real time neutron dating).
- Gamma spectrometry method (prospective search for more interesting peaks, capture study for certain actinides, and digital counting channel enabling work at high counting rates).
- Design of new fission chamber type sensor, back to back, new reference detector for absolute measurements (this item is part of dosimetry).

The aim of this action plan to control experimental uncertainties includes:

- Exhaustively taking into account sources of uncertainties
- Eventually achieving reduced and controlled uncertainties
- Reliably predicting uncertainties related to the physical parameters of an experiment

Furthermore, this instrumentation improvement project could be associated with an *instrumentation platform* where EOLE would be the core for developing new experimental techniques, which is currently a solution to overcome an important step in qualifying calculation schemes: it is also important to make an effort on experimentation as part of an effort to perpetuate and improve instrumentation and optimize the management of uncertainties.

Obviously, at the center of this experimental platform will be the X-MODE project, which is a true instrumentation and physical measurement system. Its aim is the development of this innovative measuring channel by implementing an instrumentation platform and active participation in the development of data acquisition, reduction, and analysis algorithms.

3.14 Support for Generation IV Reactor Concepts

A final line of research could be the qualification of calculation schemes supporting the generation IV reactor concept and notably HTRs (GT-MHR), hence the need for a neutron calculation tool qualified with the specificity of HTRs whose physics are completely different from those of water reactors.

A final line of research could be the study of light water supercritical reactors, again within the framework of the Generation IV forum.

3.15 Conclusions

Since its first criticality in 1965, EOLE has provided high-quality experimental programs recognized by all “customers” requesting experimental data to qualify their calculation schemes or to check the feasibility of new reactor concepts.

Conducting experimental programs for 20 years with the Under-Moderated Reactor-ERASME, PWR-EPICURE, RMA MISTRAL, and BWR programs with BASALA and FUBILA, in addition to selling experimental results, have enabled the facility to be profitable, allowed for continuous maintenance to uphold deadlines, and have maintained operating and safety teams, and especially reactor physicists at a high level of expertise.

These programs also enabled the upgrading and improvement of instrumentation and experimental measuring methods which make the facility competitive and of high quality.

Today, EOLE can offer new programs such as PERLE and FLUOLE in support of the EPR heavy reflector and the fluence of PWR tanks and sees a promising future; other programs of interest for industrial companies and CEA are on the horizon.

4 Description of the MINERVE Reactor

4.1 General Description

The reactor is built in a 120 m^3 rhomb-shaped stainless steel cavity. The moderator is ordinary demineralized water purified in filters and ion exchange resins. The core is submerged under 3 m of water and is cooled through natural convection. The maximum power is 100 W, which corresponds to a thermal flux of $10^9 \text{ n cm}^{-2} \text{ s}^{-1}$.

The core is divided into two zones:

- The driver zone comprises material testing reactor (MTR) type aluminum/uranium alloy plate assemblies, 3 m below water. It is surrounded by a graphite reflector
- The measuring zone receives experimental lattices introduced into a $70 \times 70 \text{ cm}^2$ cavity in the center of the driver zone. This experimental zone reproduces characteristic neutron spectra with light water lattices (MELODIE), fast RSMs (MORGANE-S and MORGANE-R), with sodium coolant (ERMINE), even heavy water (ELOISE)

The reactor is controlled using four hafnium rods operating both in control or safety mode.

The entire instrumentation and control system and the reactor control room, were renovated in 2002 (► [Figs. 23–25](#)).

■ Figure 23
Overall view of the MINERVE reactor

4.1.1 The Cavity

The reactor is built in a 4×5 m, and 6 m deep stainless steel rhomb-shaped cavity.

4.1.2 Driver Zone Fuel Elements

This involves MTR type fuel elements made up of 90 or 93% ^{235}U enriched aluminum-uranium alloy plates. These plates are aluminum plated and assembled in elements containing 9, 12 or 18 plates each.

4.1.3 The External Reflector

This comprises aluminum-plated graphite blocks. It allows the critical mass of the core to be reduced.

■ Figure 24
MINERVE artist drawing

■ Figure 25
MINERVE reactor control room

■ **Figure 26**
MINERVE reactor lower table and grids

4.1.4 The Central Cavity

The fuel elements and external reflector elements are distributed between four grids which can move simultaneously on the table supporting them along the two diagonals, by freeing a square at the center with sides which can vary between 0 and 900 mm (🔗 [Fig. 26](#)).

4.1.5 Control-Command

Neutron control is performed by two start-up channels and two high-level channels equipped with boron-lined fission chambers.

Command is provided by four identical control and safety rods, comprising two stainless steel plated natural hafnium plates, which slide to the center of a 93% ^{235}U enriched aluminum-uranium 12 plate fuel element.

The rods are coupled with the raising–descending mechanisms using electromagnets, which allow a drop through gravity to take place.

4.2 Advantages of the MINERVE Reactor

The main advantages of the MINERVE reactor lie in:

- *The precision of measurements* carried out through the oscillation technique with the aim of determining the reactivity weight of samples containing studied materials (dopant isotopes, alloys, irradiated fuels). The measurements guarantee reproducibility of approximately 1%, or an absolute uncertainty of approximately 0.1 pcm on samples with a reactivity weight of approximately 10 pcm. Eventually, after interpreting experiments, taking into account the uncertainty of measurement reproducibility ($\sim 1\%$), the uncertainty linked to the material balance of samples ($\sim 2\%$), and the uncertainty of modeling ($\sim 2\%$), an uncertainty of approximately 3% is obtained on the absolute reactivity weight of samples.

Currently, the oscillation technique alone allows reactivities to be determined with such precision. However, the CEA Valduc B equipment can also be mentioned as another experimental tool which allows reactivity measurements to be taken with excellent precision. This apparatus allows the reactivity of samples (liquid or solid) placed in the center to be determined through the rising water subcritical approach technique. The uncertainty on experiments, at approximately 100 pcm, however requires the use of samples corresponding to several thousand pcm, therefore containing large quantities of dopants. The result obtained is therefore no longer related only to the isotope studied in infinite dilution, and only isotopes available in large quantities can thus be used. Therefore, measurements carried out in the B equipment are complementary to those carried out in MINERVE: they represent industrial configuration geometries and do not constitute fundamental experiments.

It should be noted that MINERVE is the last reactor in the world in which oscillation experiments are carried out further to the shutdown of the UKAEA Dimple reactor. In the past, oscillation measurements were also carried out in the MARIUS, CESAR, and MASURCA reactors at CEA Cadarache. Furthermore, MINERVE is unique in that it carries out constant power oscillations, i.e., by maintaining the reactor critical through an automatic pilot rod. This technique is more precise and differs from that traditionally used, for example, in Dimple, which consists in monitoring and allowing the reactor to evolve (successive divergences and convergences) during oscillations, then in tracing the reactivity through occasional kinetic equations.

- *The flexibility in terms of neutron spectra:* It is possible to cover the full range of neutron spectra, from a very thermalized spectrum representative of a dissolver to a fast spectrum, passing PWR, PWR-MOX, BWR or epithermal type spectra. It is obviously possible to create experimental lattices adapted to future concepts (RCG, HTR) at the MINERVE plant.
- *The low cost of experiments:* Experiments are generally conducted in already existing core configurations, or which do not require the supply of new fuel, hence a low cost for experiments. The main cost stems from manufacturing oscillation samples which contain, due to the reactivity effect targeted at roughly 10 pcm, small quantities of materials and/or dopants (approximately 50 and 0.01 g give or take a few grams, respectively depending on the isotope) and therefore remain relatively inexpensive. These small quantities of dopants to be used often facilitate the feasibility of the experiment given the rareness of some of them, and allow selective integral information to be obtained with respect to the isotopes studied.

It can also be noted that a new safety calculation scheme was created in 2004. It relies on recent and qualified calculation codes: TRIPOLI4, APOLLO-2, and MCNP4C.

4.3 Coupled Assemblies

In order to obtain the most exhaustive possible qualification base for calculation forms, a wide range of neutron spectra can be used in MINERVE. The following experimental lattices have been designed using MELODIE (➤ Fig. 27), MORGANE (➤ Fig. 28), and ERMINE assemblies (➤ Table 1).

The moderating ratios and slowing down densities at the cut-off (at 2.77 keV) of the various light water experimental lattices are given in (➤ Table 2).

■ Figure 27
MELODIE assembly

■ Figure 28
MORGANE assembly in MORGANE-R configuration

Table 1
List of assemblies and configurations currently possible in MINERVE

Assembly	Experimental lattices	Neutron spectrum
MELODIE	R2-UO ₂	Dissolver spectrum
MELODIE	R1-UO ₂	UO ₂ PWR spectrum
MELODIE	R1-MOX	MOX PWR spectrum
MELODIE	BWR	BWR spectrum
MORGANE	MORGANE-R	RCVS type epithermal spectrum
MORGANE	MORGANE-S ^a	Closed RSM type epithermal spectrum
ERMINE	ERMINE ^a	Fast spectrum

^a Additional studies must be conducted for these configurations, concerning the adaptation zone between the driver zone and the center of the experimental lattice

Moderating ratio and slowing down current
($E_c = 2.77$ keV) of light water lattices in MINERVE

Experimental lattice	V_m/V_f	q
R2-UO ₂	1.4	0.80
R1-UO ₂	1.4	0.60
R1-MOX	1.4	0.55
MORGANE R	0.9	0.35
MORGANE S	0.5	0.32

4.3.1 MELODIE Assembly Representative of Pressurized Water Lattices

General Description

The MELODIE assembly (see  Fig. 27) is a 71.2 cm diameter cylinder.

The center of the MELODIE internal structure comprises a lower grid and an upper grid made of aluminum, drilled with 801 holes with a pitch of 1.26 cm, connected by aluminum tubes ($\varnothing 0.970 \times 1.10$ cm) which are used as an over-shield for the fuel. This zone forms a cylinder with a diameter of approximately 40 cm.

On a stainless steel bottom plate, aluminum blocks are arranged sideways which, on the inside, follow the contour of the grids, and on the outside are turned to a diameter of 71.2 cm.

R1-UO₂ Lattice Representative of a UO₂-PWR Spectrum

The MELODIE R1-UO₂ lattice is representative of UO₂-PWRs. It was optimized to have the spectrum of a PWR in normal operating conditions at the center of the oscillation channel, but also on a wide area around the channel.

■ **Figure 29**
R1-UO₂ experimental lattice

In this configuration (see ► [Fig. 29](#)):

- Seven hundred and seventy-six cells contain a MINERVE II type ²³⁵U 3% enriched UO₂ rod (second manufacturing series of MELODIE rods)
- Twenty-four cells placed on the periphery of the lattice contain aluminum rods
- The central cell receives the oscillation rod

Numerous experiments have been conducted in this lattice. They showed the adequacy of the lattice for representation of a UO₂-PWR spectrum.

R1-MOX Lattice Representative of a MOX-PWR Spectrum

The R1-MOX experimental configuration (see ► [Fig. 30](#)) was optimized to represent a UO₂-PuO₂ fuel PWR lattice, allowing oscillation measurements to be taken in a MOX spectrum.

In this configuration, at the center of a lattice of MINERVE II type ²³⁵U 3% enriched UO₂ rods (584 rods), a 13 × 13 cell UO₂-PuO₂ assembly is formed including:

- One-hundred and twenty four central cells containing MINERVE III type UO₂-PuO₂ rods (third manufacturing series of MELODIE rods loaded with 4% Pu)

■ **Figure 30**
R1-MOX experimental lattice

- Twenty-eight cells around the periphery of the latter, containing MINERVE III type UO₂-PuO₂ rods loaded with 3.6% Pu and placed near the corners (simulation of MOX assembly zoning)
- One central cell for the oscillation rod

Previous experimentations conducted in this lattice proved the adequacy of the R1-MOX configuration to take measurements in a MOX PWR spectrum.

R2-UO₂ Lattice Representative of a Dissolver Spectrum

The MELODIE R2-UO₂ experimental lattice was optimized in order to represent the prevailing spectrum in a dissolver in the oscillation channel.

This configuration (see ► [Fig. 31](#)) is in the same form as R1-UO₂, with the exception of a 3 × 3 cell central water hole which allows the well-heated desired spectrum to be obtained in the oscillation channel. Seven hundred and sixty eight cells contain a MINERVE II type ²³⁵U 3% enriched UO₂ rod.

R2-UO₂ was used in 1996 and 1997 for burn up credit studies applied to a Reprocessing Plant dissolver and therefore proved its capability for taking measurements in a dissolver spectrum.

■ Figure 31
R2- UO_2 experimental lattice

BWR Lattice

The BWR lattice (see ► Fig. 32) is identical to R2- UO_2 , with the exception of its center comprising an $11.34 \times 11.34 \text{ cm}^2$ aluminum block (or equivalent to nine cells), drilled in the center with a 15.5-mm diameter channel.

The BWR lattice was used in 2000 and 2001 for burn up credit studies in the BWRs and therefore proved its capability for taking measurements in a BWR spectrum.

4.3.2 MORGANE Assembly for Lattices Representative of Under-Moderated Reactors (RSM)

General Description

MORGANE S and R lattices were optimized in order to conduct reactivity loss studies by cycle in Closed type (MORGANE S) and realistic MORGANE R type under-moderated lattices, corresponding to studies on RSMVS (spectrum variation and high conversion rate reactor) concepts.

■ Figure 32
BWR experimental lattice

The experiments conducted on these lattices showed the adequacy of these blocks in representing epithermal spectra.

MORGANE-R Lattice

MORGANE R comprises a triangular “realistic” RSM lattice with a pitch of 10.35 mm (moderating ratio $V_m/V_c = 0.9$). In the center, it includes 499 $\text{UO}_2\text{-PuO}_2$ rods of graphite-gas natural uranium (UNGG) origin with 8.5% fissile plutonium, and 162 UO_2 rods enriched with 3.5% ^{235}U used as an adaptation zone (see ➤ [Figs. 28](#) and ➤ [33](#)). The experimental lattice (661 rods in total) is installed inside the structure of the ERMINE block. The space between the lattice and the structure is filled with AG 4.5 sections (see ➤ [Fig. 28](#)).

MORGANE-S Lattice

MORGANE S comprises a triangular “closed” RSM lattice with a pitch of 9.45 mm (moderating ratio $V_m/V_c = 0.5$). At the center, it includes 721 $\text{UO}_2\text{-PuO}_2$ rods with 8.5% fissile plutonium of UNGG origin (499 rods) and of PWR origin (222 rods), and 528 UO_2 rods enriched with 3.5% ^{235}U used as the adaptation zone (see ➤ [Fig. 34](#)). The experimental lattice (1,249 rods in total) is installed inside the structure of the ERMINE block. The space between the lattice and the structure is filled with AG 4.5 sections (see ➤ [Fig. 28](#)).

■ Figure 33
MORGANE-R lattice

4.3.3 ERMINE Assembly for Fast Neutron Multiplier Lattices

In the current version (ERMINE 5), the measuring zone is placed in a sealed chimney with a 735 mm diameter cylinder-shaped tube rising above the water level. The constituent elements of the studied lattice are assembled in a block that is then installed in the chimney. These elements include fuel, generally in the form of oxide mandrels, containing approximately 50 kg of plutonium or ^{235}U , sodium and steel (► Fig. 35).

The ERMINE block is an experimental block that can hold several experimental lattices representative of fast spectra. Several lattices (see ► Table 3) have previously been created and experimented in MINERVE. It should be noted that the fuel used comes from the MASURCA reactor.

The interpretations made on this lattice showed, however, that it is necessary to refine the adaptation and filtering of the spectrum between the experimental zone ZONA1 and the driver zone of MINERVE (thermal neutron/fast spectrum coupling established in a wide zone around

■ Figure 34
MORGANE-S lattice

the oscillation channel). Moreover, creating other assemblies representative of future fast neutron reactor concepts is foreseeable in the future: gas fast reactor (GFR) for example, or “fast moderated” type assembly for incineration, located between MORGANE S’s pure fast and hard epithermal spectrum (➤ [Fig. 36](#)).

4.3.4 ELOISE Assembly for Heavy Water Moderated Lattices

The measuring zone placed at the center has a tight aluminum container filled with heavy water and crossed by vertical channels in which natural uranium or slightly enriched fuel elements are placed.

5 Experimental Programs in the MINERVE Reactor

The reactor went critical on 29 September 1959 at CEA Fontenay-aux-Roses. The main experimental programs carried out since 1959 are detailed below.

Figure 35
ERMINE assembly

Table 3
Characteristics of the ERMINE-5 lattice

ERMINE lattice (740-mm diameter)	Fuel		Thinner	Observations
	Nature	Average enrichment (%)		
OU 10	UO ₂	7	SS	Uranium at 27% ²³⁵ U Small proportion of thinner
OP 40	UO ₂ -PuO ₂	10	SS	Plutonium at 45% ²⁴⁰ Pu Small proportion of thinner
OP 20	UO ₂ -PuO ₂	7	SS	SNEAK plutonium: grid strap lattice Small proportion of thinner
OP 11	UO ₂ -PuO ₂	7	SS Na	Plutonium at 8% ²⁴⁰ Pu
R 3	Metal U	15	SS Na	Uranium at 30% ²³⁵ U
RONA 3	UO ₂	13.5	SS Na	Uranium at 27% ²³⁵ U
ZONA 3	UO ₂ -PuO ₂	13.5	SS Na	Plutonium at 18% ²⁴⁰ Pu
ZONA 1	UO ₂ -PuO ₂	20	SS Na	Plutonium at 18% ²⁴⁰ Pu

Figure 36
ELOISE assembly

5.1 Main Programs Achieved Between 1959 and 1990

Up to 1966

MINERVE was first used mainly for thermal cross section and resonance integral measurements, and for studies on recycling plutonium in natural uranium systems.

- Neutron studies
 - Measurement of complete and incomplete fuel element reactivity weights
 - Measurement of spectra through activation of detectors and fission chambers
- Measurements of absorption resonance integrals in a 45×45 mm cavity: Mn-Fe-Co-Ni-Zr-Mo
- Measurements on cells simulating a heavy water system core

Two types of cells were simulated in the MINERVE cavity.

They were used:

1. To develop the local signal technique
2. To study the neutron characteristics of plutonium for a known spectrum with samples of uranium containing small amounts of plutonium or boron
3. To measure the overall capture of fission products with samples of uranium at 1.6% irradiated in EL3 (ELOISE lattice)

The results were to be used to validate calculation forms for worn fuel elements.

From 1966

In 1966, the first thermal-fast critical assembly of the ERMINE series (Expérience Rapide MINerve – Minerve Fast Experiment) was conducted in MINERVE, which comprised the driver zone, the transition zone, and the experimental zone.

At the time, MINERVE was dedicated to studies for the fast neutron reactor field conducted by placing much more subcritical volumes of different fast neutron multiplier lattices in MINERVE's central cavity (ERMINE).

Up to September 1967 – ERMINE 1

Measurements of reactivity coefficients, through the oscillation method, for a certain number of materials.

Measurements of spectral indexes.

Source oscillations.

Comparison of U8/U5 indexes with those measured in HUG (HARMONIE reactor).

From October 1967 – ERMINE 2

Metal uranium–plutonium fuel.

U1-P1-U2-P2 cores.

Doppler effect measurements on uranium-238.

From March 1969 – ERMINE 3

Metal uranium–plutonium fuel

Cores at $k_{\infty} = 1$ -KP1-KP2-KU-UK1-UK5 (European collaboration)

Heterogeneity studies

- Grid strap fuel – HP
- Terminal block fuel – H1–H2

Qualification of calculations on heterogeneity studies

HO cores – terminal block fuel

Experiments with measurement of the local signal and overall signal; measurement of the capture ratio on Pu-239 fission

From November 1971

Alternate creation of ERMINE 4 and ERMINE 5 “fast” cores and MELODIE cores (light water).

In particular, the following were carried out:

In ERMINE 5 (oxide fuel) the following configurations:

OP 10–OP 20–OP 40–OP 41–OP 50–OP 51 at $k_{\infty} = 1$, measurements taken as part of the PLUTO program, between MASURCA and MINERVE, for the qualification of plutonium (oxide) fuel cores.

ZONA 1–ZONA 2–RONA 3, for the qualification of codes involving the capture of fission products in fast neutron reactors.

In MELODIE 1–2–3 cores, UO₂ VENUS rods:

- First qualification of light water fuel lattices.
- Measurement of the capture of fission products on the SENA plant fuel.

In MELODIE 4, 17×17 PWR type – UO_2 rods:

- Qualification of the 17×17 type PWR lattice.

On 30 April 1976, the MINERVE reactor operated for the last time at Fontenay-aux-Roses

Its transfer and reinstallation at Cadarache took place in 1976 and 1977, as part of decentralization measures aimed at grouping the majority of CEA critical experiments outside the Paris region.

From September 1977, the light water and fast configurations were installed alternately in MINERVE.

In MELODIE 4 the following were carried out:

- An initial qualification of gadolinium based burnable poisons
- The EURATOM program on recycling PWR plutonium and qualification of French tools as part of the system becoming French
- Doppler effect studies
- Studies on the capture section of gadolinium, used as burnable poison

In ERMINE 5 the following were created or carried out:

- RONA 3–ZONA 1–ZONA 3 cores, for the study of fission product capture
- OA 10 and ON 10 cores for the study of the absorption section of steel and nickel
- Heterogeneity studies between grid strap and terminal block fuels (four cores)
- A degraded spectrum core. Qualification of the CARNAVAL code
- The ZOCA 13 core (plutonium). Measurement of the Doppler effect
- The ROCA one core (uranium). Study of the absorption section of structure materials

From the second quarter of 1986, MORGANE experiments to study under-moderated type light water lattices (RSM) were conducted in MINERVE (UO_2 – PuO_2 fuel). The aim was to measure the overall capture of fission products through oscillation of irradiated fuels. The following lattices were therefore studied:

- MORGANE-S: Closed pitch ($V_m/V_f = 0.5$)
- MORGANE-R: Realistic intermediary pitch ($V_m/V_f = 0.9$)

In 1987–1988, the P/A experiment (Assembly power/Internal instrumentation activity) was conducted in the MELODIE PWR block. This experiment established an experimental basis for qualification of the use of internal instrumentation of a PWR in the case of mixed loading with MOX assemblies, particularly useful for the start-up of PWR 900 moxing in Saint Laurent B1.

5.2 The CREDIT BURN UP Program (From 1993 to 2001)

The CREDIT BURN UP experimental program stems from the growing interest for the consideration of fuel wearing in criticality–safety. Between 1993 and 2001 it was the subject of a joint program between CEA and COGEMA.

The aim was to optimize the various facilities of the cycle with respect to criticality–safety constraints, more specifically, the consideration of minor actinides and stable and non-gaseous absorber PFs, enabling significant improvement of the dimensioning of facilities for the storage, transport, or reprocessing of fuels.

The following experiments were carried out as part of this program:

- Reactivity measurements in the MINERVE reactor in order to take into account the negative reactivity of products formed with the wearing of the fuel (fission products, and major and minor actinides)
- The poisoning effect of each of the 15 Fission Products PFs selected for credit burn up, with the oscillation of UO_2 samples doped with a separate isotope
- The analysis of the main absorber (and non gaseous) FPs in irradiated samples to qualify the calculation of inventory

In a more detailed manner, the program in MINERVE enabled the qualification of absorption cross-sections for 13 credit burn up fission products: ^{147}Sm , ^{149}Sm , ^{152}Sm , and Sm nat , ^{143}Nd , ^{145}Nd , and Nd nat , ^{155}Gd , ^{153}Eu , ^{103}Rh , ^{95}Mo , ^{99}Tc , ^{133}Cs , ^{109}Ag and Ag nat , Ru nat . The reactivity loss with mass combustion was also studied through measurements on sections of fuels with various combustion rates: PWR-UOX irradiated from 20 to 60 GWj/t (Bugey-3, Fessenheim-2, Gravelines-3), fresh MOX and BWR-UOX irradiated up to 45 GWj/t (Gundremmingen).

These measurements took place in four types of spectra corresponding to the following four different experimental lattices: R1- UO_2 (standard PWR spectrum), R2- UO_2 (spectrum representative of a dissolver), R1-MOX (PWR-MOX spectrum), and BWR (boiling reactor spectrum).

5.3 The CERES Program (From 1992 to 1995)

The CERES program stems from collaboration between the research centers at Winfrith and Cadarache, as part of official CEA/UKAEA collaboration on water reactors. Its objective was to provide an experimental benchmark for the validation of nuclear data (in particular JEF2.2) on actinides and on fission products used to calculate fuel burn-up and for criticality studies. The WIMS calculation code was used at AEA, and APOLLO-2 at CEA, as well as the CRIBLE criticality form.

For this, experiments conducted in the DIMPLE reactor at Winfrith and MINERVE reactor at Cadarache were conducted based on common samples manufactured at Cadarache. In addition to the measurements, the material balance of samples was analyzed at CEA Cadarache.

In 1993, phase I of the CERES program consisted in measuring reactivity for the following fuels: fresh UO_2 (from 0.25 to 5.1% U-235 enrichment), fresh $\text{UO}_2\text{-PuO}_2$ (from 0.4 to 9.56% Pu content) and irradiated UO_2 (Fessenheim and Bugey) from 20 to 60 GWj/t. In DIMPLE, the reactivity effects were obtained by measuring doubling time in three different spectra:

- Assembly I: spectrum thermalized by ordinary water
- Assembly II: “hard” PWR spectrum: lattice of UO_2 rods enriched with 7% U-235
- Assembly III: maxwellian spectrum: heavy water tank at the center of DIMPLE

In MINERVE, the measurements were taken within the framework of the CREDIT BURN UP program in the R1- UO_2 core configuration (see  Sect. 5.2).

In 1994, phase II was dedicated to measuring samples containing separated or natural fission products, diluted either in a nat UO_2 matrix, or in an aluminum-silicate matrix, or in solution in nitric acid. The experiments were carried out in assemblies II and III of DIMPLE, and in MINERVE/R1- UO_2 (for nat UO_2 samples + fission products).

Phase III of the program was the subject of wider collaboration between CEA, UKAEA, BNFL and Sandia. The CEA samples provided were of fresh MOX, irradiated MOX ($\sim 25 \text{ GWj/t}$) and nat UO_2 + fission product type. AEA/Sandia samples were of irradiated PWR and irradiated BWR type. The measurements were carried out in assembly I of DIMPLE and in MINERVE/R1- UO_2 .

5.4 The High Burn-Up (HTC) Program (From 2003 to 2004)

The HTC program (Haut Taux de Combustion – High Burn Up) is part of an R&D program in partnership with EDF and FRAMATOME.

It is split into two parts. The first is dedicated to chemical and isotopic analysis of irradiated fuels. The second consists of oscillation experiments on irradiated fuel sections in the MINERVE reactor. The objective is to improve knowledge on the loss of reactivity of the UOX and MOX fuel during irradiation.

The HTC program on MINERVE deals within the framework of increasing the time the fuel spends in the cores of French electronuclear reactors and the increased use of MOX fuel and the need to qualify changing neutron calculation schemes.

The program has been divided in two phases:

- PWR-MOX for MOX fuels irradiated (Dampierre-2) from 1 to 5 cycles (from 10 to 55 GWj/t) in 2003
- PWR- UO_2 for UO_2 fuels irradiated (Cruas-2 and Gravelines-5) from 1 to 6 cycles (from 50 to 70 GWj/t) in 2004

Spectral index, conversion and capture rate and axial and radial reaction rate distribution measurements were also carried out in order to refine neutron characterization of the lattices studied.

For light water reactors the HTC program contributed:

- To studies on high burn up rates and on increasing the time the fuel spends in the core of electronuclear reactors
 - The evolution of fuel should be controlled over time for high irradiation rates. The interpretation of experiments now contributes to the qualification of the APOLLO-2 code, notably the R2 extended qualification report
 - To studies on credit burn up by extending the qualification range to high burn up of UOX and MOX assemblies
 - More generally, in association with isotopic analysis experiments on irradiated fuels, the program enables studies on storage, warehousing, transportation, and reprocessing to be completed
- To the improvement of basic nuclear data on constituent isotopes of irradiated fuel samples.

5.5 The VALMONT Program (2003–2004)

Within the framework of JHR definition studies and the elaboration of the preliminary safety report for the latter, the VALMONT program (Validation of uranium Molybdenum Aluminum fuel for Neutronics – Validation du combustible ALuminum MOlybdène uranium pour la Neu-Tronique) was carried out in late 2003 and early 2004 in the MINERVE reactor, in order to improve precision on the reactivity and reaction rates of the new UAlMo fuel.

It was aimed at qualifying, from a neutronics standpoint, a set of tools needed to design the JHR, called HORUS3D (HOrowitz Reactor simulation Unified Lattice). The issues of the program address the wider issues of the HORUS3D form, that is to say:

- Controlling neutron calculation within the framework of safety studies
- Quality: qualification enables exact assessment of results uncertainties and contributes therefore to correct assessment of performances to be reached
- Savings, in the sense that insufficient control of uncertainties and limits of a form lead to significant and therefore expensive design margins

VALMONT is split into two distinct parts:

- The study of UAlMo fuel reactivity effects through oscillation of samples.

The VALMONT oscillation samples (see ► [Table 4](#)) were manufactured at CERCA Romans. They contain variable concentrations of aluminum, molybdenum and uranium, which enabled the study of differential effects linked to the density of the fuel, the ^{235}U enrichment, the molybdenum content, and the nature of the base.

- The study of production and neutron absorption effects, through measurements using a dedicated fuel rod containing UMo/Al enriched with 19.75% ^{235}U .

The reaction rate axial and radial profiles as well as the ^{238}U modified conversion rate measurements were carried out through gamma spectrometry near the UMo/Al rod.

■ Table 4

Samples for the VALMONT program

Sample	Characteristics
APur	Pure Al_2O_3 , used as a reference
UappAl	UAl_x containing low-density depleted uranium (2.2 g U cm^{-3}), to assess the effect of the ^{238}U
UAl20	Low-density UAl_x enriched with 19.75% uranium, to measure the influence of the enrichment
UMo/Al 2.2	Low-density UMo/Al enriched with 19.75% uranium, to measure the influence of the molybdenum
UMo/Al 8	High-density JHR reference fuel, enriched with 19.75% uranium (8 g cm^{-3}), to assess the impact of density

5.6 The ADAPh Program (2005)

As part of designing the JHR (“Jules Horowitz Reactor”) irradiation reactor, significant work was dedicated to the elaboration and qualification of a recommended neutron/thermo hydraulic coupled calculation scheme, called HORUS-3D (Jules HORowitz Reactor Unified System).

The ADAPh program (Improvement of Basic Photon Data) in MINERVE has been used as a support for qualification of the HORUS-3D-P tool intended to calculate the photon heating of JHR reactor devices. It was a support element during presentation of the preliminary safety report (PSR) around 2008.

It is part of the continuation of the ADAPh program carried out in the EOLE reactor in 2004. It aims at both reducing calculation-experiment deviations and if possible, decreasing uncertainties on experiments. The other objective is to obtain measurements in a UO_2 neutron spectrum which is more representative of the JHR spectrum than the MOX spectrum of the BASALA program.

The first phase of the program took place in January 2005 and used thermo-luminescent detectors (TLD), inserted, after calibration, in the center of the MINERVE reactor in R1- UO_2 configuration (neutron spectrum representative of a PWR- UO_2).

The second phase of the program (May 2005) was dedicated to measurements by gamma ionization chamber. These, on the one hand, helped obtain measurements separate from those given by the TLDs, and on the other hand, helped assess the contribution of delayed photons more accurately through a pulsed recording on line.

5.7 The OSMOSE Program

The OSMOSE (Oscillations of Isotopes in Eupraxic Spectra in Minerve–Oscillations dans Minerve d’isotopes dans des Spectres Eupraxiques) experimental program was designed within the framework of CEA/EDF joint work. It has also been the subject of I-NERI collaboration between DOE and CEA since 2001.

The program took place between 2005 and 2008.

The aim of OSMOSE is to gain more knowledge on basic nuclear data on heavy isotopes. The goal is both to improve calculation forms and for LWR, FBR and hybrid reactors, to back up studies on reactor physics, plutonium multi-recycling, incineration and the transmutation of actinides, storage and warehousing, and credit burn-up through heavy nuclei and fission products. This program significantly contributes to the JEFF3 project, for the qualification of actinide nuclear data.

It complements the CREDIT BURN-UP program, which it follows on the facility, and which involves absorber PFs.

More specifically, the OSMOSE program aims at providing specific experimental data (absorption cross-sections) on heavy nuclei: ^{232}Th , ^{233}U , ^{234}U , ^{235}U , ^{236}U , ^{238}U , ^{237}Np , ^{238}Pu , ^{239}Pu , ^{240}Pu , ^{241}Pu , ^{242}Pu , ^{241}Am , ^{243}Am , ^{244}Cm , and ^{245}Cm .

The study using the nuclei oscillation technique took place on a wide range of neutron spectra (PWR- UO_2 , PWR-MOX, dissolver, RSM type epithermal) corresponding to various experimental lattices.

The samples consisted in the homogeneous integration of a dopant actinide into a sintered nat UO_2 matrix. They are manufactured in ATALANTE at CEA Marcoule. The 8.1-mm diameter

and 95-mm high pellet column is inserted into a Zircaloy4 welded and tight double cladding, with a diameter and height of 10.6 and 103.5 mm, respectively.

5.8 The OCEAN Program

The OCEAN (Oscillation en Coeur d'Echantillons d'Absorbants – Core Oscillation of Neutron Absorber Samples) experimental program was supported by EDF and CEA. It took place from 2005 to 2008.

On the one hand, OCEAN is aimed at improving knowledge on absorber isotope basic nuclear data, and on the other hand, qualifying neutron calculation codes for burnable poisons and new absorbers for light water reactors. The goal is both to improve calculation forms and to study the feasibility of new fuel cycle options.

This program contributes significantly to the qualification of JEFF3 assessments. In particular, it addresses the need to conduct new experiments to improve knowledge of resonance integrals of hafnium isotopes.

More specifically, the OCEAN program aims at providing specific experimental data (capture cross-sections) on the following isotopes: Gd-155, Gd-157, Gd-nat, Hf-177, Hf-178, Hf-179, Hf-180, Er-166, Er-167, Er-168, Er-170, Dy-160, Dy-161, Dy-162, Dy-163, Dy-164, Eu-151, Eu-nat, Eu-153.

The study using the nuclei oscillation technique took place on a wide range of neutron spectra (dissolver, PWR-UO₂, PWR-MOX, epithermal (RSM type)) corresponding to various experimental lattices.

The samples consist of an absorber dopant mixed homogeneously in a sintered nat UO₂ matrix. They are manufactured at the Fuel Research Department at CEA Cadarache. The 8.1-mm diameter and 95-mm high pellet column is inserted into a Zircaloy4 welded and tight double cladding, with a diameter and height of 10.6 and 103.5, mm respectively.

Spectral index, conversion and capture rate, and reaction rate axial and radial distribution measurements were also carried out in order to refine the neutron characterization of studied lattices.

5.9 Training Activities

5.9.1 EDF Training

Since 2004, the MINERVE reactor has been used to support training for future EDF operators. This activity takes up approximately 1 month/year, and should remain the same or be slightly less in the future.

5.9.2 INSTN Training

Since 1998, MINERVE has also been used within the framework of practical work for Atomic Engineering training for the INSTN Cadarache. From time to time, practical work for radio-protection *Brevets de Techniciens* (BT and BTS – technician diploma) of the INSTN Cadarache have also been carried out in the past. It is used for 1 week/year.

5.9.3 Other Training

The extension of training activities to other engineering schools, master's programs or university activities is however foreseeable in the future.

5.10 The Gas Fast Reactor (GFR) Program

CEA and US-DOE have shown strong interest for an oscillation program in an GFR type core configuration within the framework of the GENERATION IV forum. Such a program would be complementary to the ENIGMA program planned in MASURCA, as it would provide experimental measurements on basic nuclear data.

This program could be carried out based on existing OSMOSE, OCEAN and CBU samples if their reactivity weight is sufficient. If this is not the case, other samples would need to be manufactured.

A feasibility study would also need to be carried out on one or several GFR configurations in MINERVE (representativity of the neutron spectrum for samples, adequacy with the maximum available space in the center of the driver zone and compliance with safety criteria).

It would also be interesting to add a Doppler study to these programs. It involves studying a sample heat-up system, which could fulfill the same functions as the one that existed in the early 1980s (HF heating). Emphasis must be placed on controlling the temperature of samples, the temperature axial profile which must be as flat as possible, and compliance with safety criteria.

Finally, reinterpretation of the PROFIL and PROFIL-2 experiments held in PHENIX Fast Reactor revealed lacks in fast spectrum in the assessment of certain fission products of the JEFF3.0 library of the ERANOS-2.0 code system. New measurements would therefore be necessary on the following PFs: Mo-95, Mo-97, Ru-101, Pd-105, Pd-106, Pd-107, Cs-133, Cs-134, Nd-143, Nd-144, Nd-145, Sm-147, Sm-148, Sm-149, Sm-150, Sm-151, Eu-151, Eu-153, and Eu-154. The feasibility of manufacturing samples containing these separate isotopes with a sufficient isotopic purity with respect to target uncertainties would therefore be interesting to study.

5.11 The HTR Program

The idea is to oscillate burn up fuel rods (or any other form of fuel representative of the HTR fuel) and/or fuel rods of different natures at the center of the configurations (to be designed) of the core, representative of HTR spectra. An experimental lattice which can be adjusted (the same way as MELODIE can be changed to R2-UO₂, R1-UO₂ and R1-MOX) can be of interest to have several points in the spectrum.

The oscillation of existing samples (OSMOSE, OCEAN and CREDIT BURN UP) would also be carried out if their reactivity weight is sufficient (~10 pcm in the thermal/epithermal spectra studied).

Carrying out a Doppler study is also foreseeable.

5.12 HTC Program Supplement

It must be reminded that the oscillation of the ALIX 75 GWj/t fuel was postponed due to the fact that this fuel was unavailable at the time of the HTC-UOX program. This oscillation remains interesting and can still be carried out.

It is reminded that the interpretation of radiochemical analyses for UOX fuels irradiated at 60 GWj/t in CRUAS2 NPP highlighted an inconsistency between the errors on the fuel inventory (high overestimation of the Pu-239 concentration) and the reactivity effect of corresponding oscillation samples (overestimation of the reactivity loss with the burn up fraction).

It would also be interesting to oscillate HBU samples in highly thermalized (R2-UO₂) and epithermal (MORGANE-R) spectra.

5.13 Program on Structure Materials and Moderators

This program is part of the issues surrounding basic nuclear data.

It involves steel, Al, Pb, Cu, Cr, Ni, and Fe type structure materials, activation products from Co-59 or Cl-35, or Be, C, H₂O, CH₂ type moderator materials. The list of materials remains open.

The required qualification of basic nuclear data was particularly highlighted during qualification studies for the CRISTAL V1 form and within the framework of an ISTC international project.

The idea would be to compare the signal of these samples with that of a vacuum filled sample.

We can also consider studying the reactivity variation of these samples according to temperature, particularly in the case of moderator materials for the study of $S(\alpha, \beta)$ treatments, linked to the crystalline structure of the material, which is involved in the neutron thermalization process.

5.14 FP and Absorber Supplementary Program

Interpretation problems due to the volatility of metallic FPs during sintering, then due to dissolution difficulties were observed during the CBU program, particularly for Ag-109, Rh-103, and Tc-99, as well as for Cs-133 due to its strong volatility. Two solutions can be selected to solve this problem:

- Carry out a destructive analysis on existing samples. This solution must however take into account the fact that current dissolutions of metallic FPs are still not fully developed. Furthermore, CBU samples in question would no longer be available for other experiments.
- Have other samples containing these PFs manufactured in a compacted nat UO₂ matrix, which would avoid the need for analyses as there is no loss of PF during compacting (as opposed to the case of sintering), then re-oscillate them in core configurations of interest. It would also be interesting to have an Sm-147 sample containing less Sm-149 “pollutant” manufactured.

Moreover, some interesting absorbers such as Gd-154, Gd-156, and Gd-158, were not selected for the OCEAN program for financial and/or insufficient isotopic purity reasons. However, the interest of manufacturing such samples is justified by the following elements:

- These pair isotopes are responsible for the residual penalty of gadolinium burnable poisons
- The problem of isotopic purity is reduced in an epithermal spectrum such as that for MORGANE-R, or all the more in a fast spectrum. There is a possibility (to be studied) of measuring these samples through oscillation with correct uncertainty. It is also possible to cut the spectrum's thermal component using a Cadmium filter, in which case the isotopic purity is no longer a problem

5.15 Program in Support of JHR for Qualification of HORUS3D for U_3Si_2

There is the possibility, if needed, of carrying out an oscillation program of approximately 3 months, of the same type as VALMONT but for U_3Si_2 (back-up fuel candidate for JHR).

5.16 Cadmium Measurements

For all programs, it would be interesting to carry out oscillations measurements on samples with Cadmium, in addition to measurements without Cadmium. This would enable:

- Elimination of thermal components from highly capturing impurities, and thus improve the uncertainties linked to the interpretation of measurements. For example, Gd-155 and Gd-157 impurities in Gd-154 and Gd-156.
- The origin of any deviations between calculations and experiments to be targeted by having information on the thermal part and on the epithermal/fast part of the signal.

This solution will be studied by CEA. It involves integrating the Cadmium into the oscillation rod, all while complying with facility safety criteria (particularly reactivity effect lower than $\beta/2$).

5.17 Other Programs

In addition to the aforementioned programs, other oscillation experiments can be planned for the future in MINERVE, within the framework of:

- Support for the French electronuclear fleet. There is the possibility of testing new fuel options in the future, or as already mentioned in ➤ Sect. 5.12, of studying increasingly higher burn ups
- International collaborations. There is the possibility of carrying out benchmarks of the same type as the CERES program in the future
- Studies on under-moderated reactors (RSM), with the possibility of creating experimental lattices other than MORGANE R and S, corresponding to intermediary neutron spectra
- The opening up towards fields other than reactor physics, such as the needs in basic nuclear data for astrophysics
- Studies on materials for the ITER project
- Support for JHR

5.18 Conclusion

Since its first divergence in 1959, the various experimental programs carried out in MINERVE helped determine integral nuclear data with high precision in various neutron spectra (thermal, epithermal, and fast).

Updating the instrumentation and control system and the oscillator further to the CREDIT BURN UP program allowed the HTC, VALMONT, OCEAN, and OSMOSE programs to be carried out with increased quality of results and an optimum level of safety starting in 2003.

These experimental programs are also based on the upgrading and development of instrumentation and experimental measurement techniques, which improve the competitiveness and quality of experiments.

In the near future, the OSMOSE and OCEAN programs will be completed between now and late 2008 in various light water lattices.

After Safety Reassessment of the Eole and Minerve facilities planned for 2010–2011, other experimental programs are being studied, to support future reactor concepts (GFR and HTR, with Doppler effect study), the current fleet (HBU supplement, structure materials, supplement to fission products and absorbers), the JHR (U_3Si_2 fuel study), or more generally to improve basic nuclear data (cadmium measurements, various needs in reactor physics or astrophysics).

6 Description of the MASURCA Reactor

The MASURCA reactor is one of the critical mock-ups from the “zero power” class, operated by CEA on the Cadarache site (Bouches du Rhône). Built between 1964 and 1965 (🕒 Fig. 37), this reactor went critical for the first time on 14 December 1966. It was authorized to operate at a maximum neutron power of 5 kW in 1969 and since then has been used mainly to study fast neutron reactors.

The MASURCA facility is located at the South-East end of the Cadarache Research Centre near the RAPSODIE reactor and the zone of the old HARMONIE reactor. The MASURCA zone comprises of four main buildings that are connected to each other through underground

■ Figure 37
Construction of MASURCA

■ **Figure 38**

■ **Figure 39**
MASURCA platform

galleries or covered passages on the surface (► [Fig. 38](#)). This approximately 6,000-m² platform is included in a zone with a total surface area of approximately three hectares surrounded by a double fence. These four buildings are (► [Fig. 39](#)):

- The reactor containment
- The control building containing control and monitoring equipment, the reactor's Control room as well as the measurement room used by researchers

■ Figure 40
View of MASURCA reactor containment

- The storage and handling building where simulation elements are stored
- The auxiliary building

The reactor building, partly buried, has a total height of 26 m (🔍 Fig. 40). It comprises a circular metal shell topped with a dome and resting on a circular base slab made of 1 m thick concrete. It comprises the reactor core supported by massive reinforced concrete inner structures, the main equipment which is used for experimentation, a vertical storage area for loading tubes as well as various handling means to allow the loading or unloading of various loading tubes in the reactor core. It also houses part of the ventilation system organs dedicated to dynamic containment of the structure and cooling the core (➡ Fig. 41).

6.1 Core Building Principles

The cores studied in MASURCA comprise a lattice of stainless steel assemblies (tubes) called “loading tubes,” which can be removed, loaded with simulation elements and attached at the upper part to rhomb shaped vessel, set with corners cut, comprising two assembled base plates. The lower base plate is drilled with bore holes to receive seals in which the tube heads are locked. The tube legs fit into bore holes on a second plate, the centering plate, ensuring the safety of the attachment, the centering of tubes and the closure of the cooling system. The centering plate is mobile and can also occupy:

Figure 42
Diagram of a MASURCA tube

- An intermediary position for handling tubes
- A lower position for handling safety rods

A maximum of 1,100 tubes can be installed, allowing simulation of cores able to reach a total diameter of approximately 3.8 m.

In practice, two types of tubes are mainly used:

- The MASURCA tube (➤ [Fig. 42](#)), comprising two stainless steel sheet metal half casings with an overall dimension of $104.9 \times 104.9 \text{ mm}^2$ for a casing sheet thickness of 1.45 mm and a total length of 3.80 m (tube head and leg included). These tubes are used to hold simulation elements in the form of terminal blocks
- The 4/4 tube (➤ [Fig. 43](#)) comprising four $2 \times 2''$ (Most dimensions typical of tubes or simulation elements are expressed in inches. This results from a historical desire to facilitate communication with other European and international critical mock-ups.) tubes connected at the head and leg in order to recreate the overall geometry similar to that of MASURCA tubes. Each $2''$ tube has the shape of a prismatic box, with a square base (of $52.5 \times 52.5 \text{ mm}$ overall, for a tube sheet thickness of 0.725 mm) with a total length equal to that of MASURCA tubes (tube head and leg included). The use of these tubes allows better flexibility when several elementary patterns must be installed in one tube. They are also often used to ensure correct roundness of various zones of the core

The control bodies associated with the core are:

- Safety rods (SR) which ensure safety of the reactor during operation and handling
- The pilot rod (PR) is used to regulate the reactor

Figure 43
Diagram of a 4/4 tube

The core includes a variable number of safety rods (between 4 and 8) depending on the characteristics and the size of cores. These safety rods are composed with absorber material (B_4C blocks or bars) in the upper part and fissile materials in the lower part with the same pattern as in the core. In normal operating, since these rods are always positioned in raised position, the homogeneity of the core is preserved (► Fig. 44).

To reach the criticality and obtain the power required for the experiments, a Pilot rod (PR) with reactivity worth less than half a dollar, is used. In order to reduce the disturbances created by such a lattice, it is composed of a fuel tube containing a mobile part made of a ^{235}U enriched rod surrounded by stainless steel in the upper part and moderator material in the lower part (► Fig. 45). Tuning the position of this Pilot rod, the criticality is obtained by moderator effect.

To carry out the measurements, special channels can be opened throughout the MASURCA tubes to introduce different measurement devices (fission chambers, monitors, foils, neutron sources): two horizontal channels at 90° around the mid-plane (radial channels) and as many axial channels as necessary (an axial channel can be arranged in any sub-assembly).

6.2 Simulation Materials

The simulation elements (fissile, fertile, reflector, inert, or absorber materials) are in the form of 1/2 in. (12.7×12.7 mm (Some fissile materials are also available in the form of 1/4 in. diameter (6.35 mm) terminal blocks.)) or diameter square or circular section terminal blocks, with a

Figure 44
View of suspension table and safety rods mechanisms

Figure 45
Diagram of the pilot rod

■ Figure 46

View of a few fissile elements (U^{235} enriched metal uranium terminal blocks)

height of 4–24 in. They are grouped together so as to form elementary patterns (generally made up of 4–8 terminal blocks) which are reproduced inside tubes. These elementary patterns (cells) allow simulation of core characteristics to be studied (volume percentage of different materials, enrichment).

The list of nuclear materials that are currently used at MASURCA includes oxide of thorium, metallic uranium with up to 35% ^{235}U , uranium oxides (depleted and enriched with 30% ^{235}U), metallic plutonium, plutonium oxide and mixed plutonium and uranium oxides with various ^{240}Pu contents (8–44%). Several types of inert materials – sodium, stainless steel, graphite, lead – are also set-up to simulate the coolant, the reflector parts, and the structure materials. The amounts available allow cores with varying fissile zone volumes to be built: the smallest core loaded was 140 l (annex x) when the largest was 3,400 l in comparison to the volume of the PHENIX core (around 1,500 l) (► Figs. 46–48).

7 Experimental Programs in MASURCA

MASURCA went critical for the first time on 14 December 1966 with a UPuFe/graphite core. After a period dedicated to studying the behavior of the facility and the development of the first experimental measurement techniques (1967–1969), the programs were first tied to basic studies as fissile materials became available (RZ and PLUTO programs). From 1976, after the industrial commissioning of the PHENIX reactor 2 years earlier, the experiments were oriented towards support for the start-up of SUPERPHENIX (PRE-RACINE, RACINE and BALZAC

■ Figure 47
Building of a fissile tube

■ Figure 48
View of a tube

programs), and the investigation of questions linked to the SPX2 and EFR – European Fast Reactor – (CONRAD program) projects. In a third period, at the instigation of the law dated 30 December 1991 on the management of long life radioactive waste, three major programs were led within the framework of axis 1 (separation–transmutation) of the law:

- From 1994 to 1997, the CIRANO program enabled the study of cores burning plutonium within the framework of the CAPRA project (Increased Plutonium Consumption in Advanced Reactors)
- From 1998 to 1999, motivated by the introduction of ECRIX experiments in PHENIX, the COSMO program examined the effects of minor actinide transmutation in heterogeneous mode in moderated targets placed in an RNR
- Finally, from 2000 to 2004, subcritical systems coupled with an external neutron source which were studied extensively during MUSE-4 experiments

A summary of the objectives and major events for each of the programs led is given in the following section.

7.1 The RZ and PLUTO Programs (1969–1975)

The main objective of the RZ program was to study material buckling according to enrichment for Uranium (R) and Plutonium (Z) cores (► [Table 5](#)). The analysis and interpretation of this program led to the development of the CARNAVAL III calculation form that enabled the characteristics of cores containing a Pu fuel with low ^{240}Pu and ^{241}Pu content to be predicted. The PLUTO program, carried out at the same time in MASURCA and MINERVE (ERMINE configurations) was aimed at improving knowledge on plutonium superior isotopes. These experiments led to the creation and qualification of the CARNAVAL IV form.

7.2 The PECORE Program (1975)

This program was conducted within the framework of collaboration with the CNEN (Italian Committee for nuclear energy) for the PEC irradiation reactor project. Two core configurations were investigated:

- The PECORE 1 configuration with an internal zone loaded with UPuO_2 fuel and external zone loaded with the R2 cell. It simulated the actual environment of the PEC reactor.
- The PECORE 2 configuration with an internal zone loaded with the R2 cell and an external zone loaded with UPuO_2 fuel (ZONA 2 cell). This configuration was put in place to study the system of PEC reactor control rods.

7.3 The PRE RACINE and RACINE Programs (1976–1984)

The RACINE program is one of the most important conducted at MASURCA in terms of its duration as well as its objectives and stakes. The objective of the program was to validate the calculation tools and schemes used for SUPERPHENIX studies and to explore, to a certain

■ Table 5

Characteristics of cores studied during the RZ and PLUTO programs

Program	Core	Year	Fissile cell	Fuel nature	Comments
RZ	2A	1969	Z2	Metal (UPuFe)	
	2B	1969, 1970	R2	Metal (enriched U)	Two cores studied: A first core with a 60-cm high fissile zone A second with a 90-cm high fissile zone First “sodium” core First measurements of the reactivity effect in the event of sodium drainage
	3B	1970, 1971	R1	Metal (enriched U)	Several axial blankets studied (depleted uranium, steel/sodium, UO ₂ /sodium)
	4B	1971	R3	Metal (enriched U)	
	4A	1971	Z3	Metal (UPuFe)	
	4B'	1972, 1973	R3	Metal (enriched U)	“Absorber rod at center” program Measurement of radial and axial “sodium” void
PLUTO	7A	1974	ZONA3	Oxide (UPuO ₂)	
	6A'	1975	ZOCO1	Oxide (UPuO ₂)	Smallest core ever created Approximately 27 cm critical radius
	PECORE 2	1975	ZONA2	Oxide (UPuO ₂)	CEA/CNEN collaboration for the PEC reactor

degree, the physical characteristics and problems of large cores. The RACINE experiments thus enabled:

- The in-depth study of the “radial composite core” concept (RACINE 1A, 1B, 1C, and 1F)
- The question of calculating the efficiency of control rods and interaction problems between rods (RACINE 1D and 1E) to be treated
- Investigation of certain questions concerning SUPERPHENIX neutron control (simulation of neutron guides)
- Examination of calculation tool performances and the experimental technique used for the “checkerboard pattern” subcritical approach selected for loading SUPERPHENIX

The measurements carried out during this program are summarized in ➡ [Table 6](#).

■ Table 6

Measurement carried-out during RACINE program

Parameter	Program phase	Comments
Reaction rate distribution	RACINE 1A	Different fertile ring positions but with the same volume
	RACINE 1B	
	RACINE 1C	Increased ring volume
	RACINE 1F	Measurements close to control rod singularities
	RACINE 1E	IRMA experiment – international benchmark for reaction rate technique inter-comparison
	RACINE 1I	
γ -Heating	RACINE 1A	Multi-laboratories inter-comparison of techniques
Control rod worth	RACINE 1D	A reference core and a configuration with a single rod at core center
	RACINE 1E	Multiple rod configurations
	RACINE 1F	Inter-comparison of rod drop analysis method (CEA/France, ANL/US, GKAE/Russia) for inserted reactivities in the range [0.25\$; 1.2\$]
Criticality approach and neutron control lattice issue	RACINE 1S	
Sodium void	RACINE 1F	

The RACINE 1A, 1B, 1C configurations were aimed at studying different configurations each with a central island and an external fertile ring. In these three configurations, the external ring was positioned differently but its volume remained the same.

RACINE 1F was aimed at studying the effects produced by a larger volume fertile ring. This core is one of the largest cores ever built at MASURCA. The external diameter of the fissile zone was approximately 2.2 m.

Two distinct experiments were interested in the calculation and measurement of the reactivity weight of control rods:

- The RACINE 1D experiment that had two configurations: a “clean” reference critical configuration and one with an absorber rod simulated in the core’s center.
- The RACINE 1E experiment for which the goal was to study the problems of interaction between rods. This experiment was an initial approach to problems raised by large cores though the separation ratio of eigenvalues is much lower than the desired values.

The main objective of the RACINE 1S program was to study the checkerboard pattern loading method selected for the start-up of SUPERPHENIX.

- Creation of two critical configurations comprising a significant number of thinner assemblies (75% steel, 25% sodium)

■ Figure 49

RACINE 1A, 1B and 1C critical configurations.
RACINE, 1F critical configuration

- Simulation of the “neutron guide” system implemented at SUPERPHENIX

7.4 The BALZAC Program (1985–1988)

Additional studies to calculate the worth of control rods and the effect of the design (heterogeneity effect). Fine simulation of rods used at SUPERPHENIX to explain the calculation-experiment deviations observed during start-up tests.

7.5 The CONRAD Program (1989–1992)

Study of the axial heterogeneous concept but with a “decoupled large core” phase (separation parameter of eigenvalues above 15) was never carried out.

7.6 The BERENICE Program (1993)

This was the international Benchmark on measuring the effective fraction of delayed neutrons (beta effective) on two different cores:

- A uranium core, loaded with the R2 cell, similar to the 2B core studied in 1969
- A plutonium core loaded with the ZONA2 cell

7.7 The CIRANO Program (1994–1997)

This program included three main phases. The first one, devoted to the study of the replacement of fertile blanket by a steel/sodium reflector, included three different configurations:

- ZONA2-A: reference core with uranium/sodium (50/50) blanket

- ZONA2-A3: change of the radial Uranium/Sodium blankets with a steel/sodium reflector (75/25)
- ZONA2-B: change of the axial Uranium/Sodium blankets with a SS/sodium reflector (75/25)

The second phase addressed the internal assembly storage zone issue. It also included three different configurations:

- ZONA2-B SI-Ref: reference configuration with an extended steel-sodium reflector
- ZONA2-B-SI1: set-up of a row of fissile tubes in the storage zone
- ZONA2-B-SI2: set-up of a row of absorber tubes between the storage zone and the core

The last phase of the CIRANO program aimed to load, in the central zone of the ZONA2B configuration, some tubes with a high Pu content and various Pu isotopic compositions. Pu content varied in the [25%; 48%]. Pu240 content varied from 8 to 33%. The objective was to carry out characterization measurements with a central zone with features intermediate between SUPERPHENIX and CAPRA (Consommation Accrue de Plutonium dans les Réacteurs Avancées – Increased Burn Up of Plutonium in Advanced Reactors).

7.8 The COSMO Program (1998–1999)

From 1998 to 1999, the COSMO program aimed to study the Physics of the irradiation of long lived fission products targets in moderated sub-assembly at the periphery of fast neutron reactors. The effects of various moderators, $^{11}\text{B}_4\text{C}$, CaH_2 , ZrH_2 , have been investigated. This program helped in particular, to prepare the ECRIX experiments that were loaded in the PHENIX reactor in 2003.

7.9 The MUSE Program (2000–2004)

Neutronic experiments, studies and the associated calculation tools have mainly been achieved in the past for *critical* reactors. Experimental techniques have also been developed, directly applied to power critical operating lattices. The same approach for studying neutronics of subcritical lattices driven by an external source is based on the decoupling of the validation of the subcritical multiplying medium behavior from the validation of the external source characteristics.

Following this roadmap, the MUSE experiment series at MASURCA constituted the first phase at zero power. From 1995, the MUSE-1 experiments then the MUSE-2 experiments, performed with a ^{252}Cf source located at the center of the MASURCA core, aimed to demonstrate that experimental measurement techniques used for critical cores could be also used for subcritical configurations. In 1998, the MUSE-3 experiments constituted the first important parametric study with the loading of several configurations with increasing subcriticality levels. Based on the use of a commercial neutron generator, once more located at the center of the core, these experiments helped, following the problems encountered in the interpretation of measurements, to define the conditions to carry out a MUSE-4 program and to specify the characteristics of a more intense and more suitable neutron source for the envisaged measurements.

The objectives of the MUSE-4 program were (1) to operate a fast subcritical core coupled with an external neutron source simulating the spallation source of an ADS without feedback effect, (2) to characterize such a lattice providing experimental data for calculation tool

validation and (3) to investigate techniques and analysis methods for subcritical measurement and monitoring.

All the configurations, representative of a fast burner reactor, were loaded with MOX fuel and sodium as a coolant. The core was surrounded, axially and radially, with a reflector composed of sodium and stainless steel. The simulation of the spallation target and the neutron source (the GENEPI neutron generator consisted of a 250 keV deuteron beam horizontally guided on a target (either TiD or TiT) located at the center of the core and surrounded by a lead buffer. To compensate the spatial effect due to the presence of the GENEPI guide in the north part of the loading, the south symmetrical part was loaded with pure lead (99.99% of Pb) simulating the Pb circulation of the target.

7.10 The Facility Refurbishment Project

Before new experimental programs within the framework of the GEN-IV forum are launched, important work will be conducted at MASURCA in order to extend its service life. This

■ Figure 50
The MUSE-4 Program: radical critical configuration

renovation program will mainly impact the electric power supplies, the back-up lattices, the handling machine, the core cooling circuits, and fire prevention. Seismic reinforcement work and the complete modification of the control room will be also carried out. This “new” facility should start by 2015–2017. Outlines of experiments in support of SFR (GENESIS program) and GFR (ENIGMA program) have already been investigated. This work is being pursued.

7.11 A Program in Support of SFR and the 2020 Prototype: GENESIS

For oxide fuel FBRs, an experimental program can be built based on the ZONA3F* or ZONA3M* cells. It is, however observed that the cells are not very reactive: $k^* \sim 1.05$ and 1.09. Therefore, in practice, it will be difficult to build a homogeneous core exclusively made up of these patterns. To maintain reasonable experimental volumes (outer diameter of the fissile zone < 1.4 m), we will have to radially create cores with two fissile zones (at least) to reach criticality: the inner zone made up of ZONA3F* cells or ZONA3M* cells, will be surrounded by a peripheral zone supplying the additional neutrons. The inner zone should be large enough for the fundamental mode to be established in the central region. The outer zone will be made up of enriched uranium-based cells, asymptotically equivalent to the inner cells.

For carbide fuel FBRs, a cell similar to ZONA3F* or ZONA3M*, but U-Pu-C fuel based, is to be created using graphite terminal blocks. The tests conducted are similar to those proposed for oxide cores.

The cores thus created will be surrounded by a radially compact zone of reflectors-shields and axially topped with a sodium plenum.

The GENESIS program, for GENERation of Experiments for Sodium-cooled Innovative Systems, will include:

- A *full neutron characterization* of the core (fundamental mode at center): reactivity, spectral index measurements at the center, material buckling, reaction rate cross-members, important cross-members, β_{eff} , etc.
- A parametric study of *sodium drainage* effects on variable height zones
- Partially or fully “drained plenum” configurations
- Study configurations for softening of the neutron spectrum in the core
- Studies of variations by *substitutions* of the following materials *at the center* of the core:
 - Deteriorated plutonium zone (+ effect of local drainage)
 - Absorbers
 - Zone made up of another fuel (carbide, metal) + effect of local drainage
 - Samples of various materials
- *Gamma heating* measurements
- Characterization measurements of core-reflector (➡ Sect. 6.2.4) and core-plenum *interface zones*

Study of the plenum drainage and drainage in the core could be limited to a central zone of approximately 20–30 tubes. In doing so, the time needed to conduct these experiments is approximately 1 and a half years: 8 months for loading and characterization of the initial configuration, 6 months to create different “drained plenum” configurations (subcritical and critical measurements), 4 months for sodium drainage experiments in the core (subcritical measurements only).

Creating these configurations, based on a single ZONA3M* type fissile cell (no peripheral driver zone), would require a complement on the stock of Pu-based fuel. Configurations implementing different patterns, from the core's center towards the periphery, can nevertheless be created with $\text{PuO}_2\text{-UO}_2$ fuel, currently in stock, and an addition of enriched metal uranium terminal blocks.

7.12 A Program in Support of GFR: ENIGMA

The ENIGMA program, Experimental Neutronics Investigation of Gas-cooled configurations in MASURCA, is devoted to GFR system generic phenomena in an initial phased of approximately 2 years. This initial phase relies on the use of current fuel stock.

Like GENESIS, this program will include a set of *physical characterization* measurements of a reference core, which will be based on the ZOGA1 cell. *Substitutions* in a central zone will be used to study the effects of streaming, the softening of the spectrum by introducing graphite, deteriorated plutonium vector fuels, the effects caused by the presence of innovative structure materials (Si, Zr), etc.

A second phase will be dedicated to studying control means. This could be accomplished by introducing an absorber rod for which the drawing would be changed, into the core's center. This study could then be conducted by moving the same rod away from the core's center to be in real conditions of a rod in a power reactor.

Finally, in a third phase, over a period of 2 years, more specific problems will be looked into, highlighted by design studies conducted within the frameworks of GEN-IV and REDT (Réacteur Expérimental et de Démonstration Technologique – Experimental and Technological Demonstration Reactor). It could be carried out with a core partially loaded with fuel (U,Pu)C (several batches with different Pu vectors) for which the supply will have been launched long enough in advance to follow through with safety studies as well as the updating of the safety report. For this reason, it can be noted that MASURCA originally had UPuFe fuel (two different fabrications with 4 and 8% Pu240 respectively) for simulation of both oxide and carbide fuels (where the oxide oxygen was provided by Iron oxide simulation elements – Fe_2O_3 – and the carbide carbon provided by graphite simulation elements). This fuel was eliminated in the early 1970s following handling problems encountered.

7.13 A “FBR Large Cores” Generic Study Program

This program is aimed at studying particular specific phenomena for FBR large cores: decoupling between the various zones, questions related to distortion of the power distribution map, interactions between absorber rods, instrumentation and detection problems in the event of incidents and/or accidents (for example, issue of handling error).

To facilitate carrying out this type of experiment, there would be a need to add to the stock of materials available at MASURCA. As a reminder, although the CONRAD-DC program (never carried out) was supposed to use all the stock (ZEBRA Pu metal included), the amplification factors of the various configurations remained nevertheless below typical values for envisaged power cores.

Due to the lack of enough fissile material to create a large volume block, this core could be created based on the ZOCO3* cell, which particularly allows the migration area of neutrons to

be diminished, and therefore neutronic conditions equivalent to those of a large core in a small block to be created. Measurements will involve the study of radial decoupling. The problem of optimal positioning of control rod curtains will be studied.

Such a program could *last* for approximately 2 years: loading and characterization of the reference configuration (10 months), characterization of decoupling effects between zones (8 months), simulation of accidental configurations (handling error, rod riser) (6 months). The study of “large core instrumentation” issues could be conducted in parallel, during the various phases of the characterization program.

7.14 A “Reflector and Shield” Program

This program is of interest for all future FBR systems, implementing various reflector and shield concepts: homogeneous reflectors of various natures like steel, SiC, ZrC, Zr_3Si_2 , heterogeneous reflectors which may contain absorber materials, more or less compact protection zones.

In order to simplify things, it is suggested that these studies be conducted on axial reflectors (30 cm high minimum) and on a radius zone limited to twenty assemblies. This solution, if acceptable (insignificant disturbances along the measuring axis), would allow procurements and the time required to change from one solution to another to be limited. A 1-year program would probably allow 4–5 different concepts to be studied.

7.15 A “Deteriorated and Accidental Configuration” Program

The purpose of this program would be to create benchmarks to check the quality of calculation predictions on configurations very different from those normally processed. This program could cover aspects such as fusion of the structure tube, fuel collapse, fuel compacting, as well as configurations with other distributions of materials.

For this type of experiment, only reactivity effects would be measured and depending on the expected variation, they could even be limited to subcritical measurements. A program of this type could therefore be carried out relatively quickly if the number of MASURCA tubes to be remodeled remains limited.

8 Experimental Methods Used and Being Developed on These Critical Mock-Ups

8.1 The Main Measuring Techniques Used

Mainly two types of measurements can be identified, which can be associated with a large number of experimental techniques:

- So-called “online” measurements, that is to say mainly monitoring fission chamber counting rates (in critical or subcritical)
- Postirradiation measurements, carried out directly on fuel rods (γ -scanning), after irradiation in the core

8.1.1 Measurements by Miniature Fission Chambers

Measurements by fission chambers can be separated into two categories, depending on the desired integral quantity to be obtained:

- *Kinetic* measurements, mainly doubling time and rod drop measurements
- *Quasi-static* measurements, where the counting rate of chambers is analyzed. They provide information on the criticality level of the core or on fission rate distributions or information on the local spectrum in the lattice

8.1.2 Measurements by γ Spectrometry

Gamma spectrometry measurements (γ -scanning) are postirradiation: they provide information on the reaction rates generated in the core. The main rates measured are fission (locally or its distribution) and radiative capture, by measurement of the total gamma activity of the fuel rod in question or that of specific isotopes (fission products or capture products). In this way, it is complementary to the measurement of distribution by fission chambers. Gamma spectrometry can be split into two complementary techniques:

- *The integral gamma scanning technique*, used for axial and radial distribution measurements in fuel rods with the same or a similar nature. It provides an averaged value in energy on the neutron spectrum. It is used to validate calculation models of assemblies, or 2D core calculation models, even 3D if an axial heterogeneity is present.
- *The specific peak technique*, also called “peak check” where the activity of a specific isotope is measured. It is used in power calibrating two integral γ -scanning maps carried out on rods of different natures, or to determine specific spectral indexes, such as the modified conversion rate.

8.2 Classification

It is not easy to process critical mock-up measurements as several approaches can be chosen:

- Classification according to measurement techniques (fission chambers or γ -scanning)
- Classification according to integral variables of interest

We have chosen the latter approach in this document. This allows information provided by measurements in terms of qualification of calculation codes to be detailed.

8.3 Measurement Electronics at EOLE/MINERVE

Measurement electronics at EOLE are used for both in core measurements, that is to say by fission chambers, and postirradiation measurements (gamma spectrometry). Measuring channels are based on a similar principle. Each channel is equipped with:

- A detector (fission chamber or diode), which enables the collection of loads associated with a specific reaction (neutron for the fission chamber, or photon in the case of spectrometry)
- High voltage (HV), connected to the detector
- A preamplifier and a load amplifier, to formulate impulses emitted by the detector

- A discriminator
- A coder
- A signal processing interface

Here, particular attention will be paid to the electronics associated with spectrometry.

8.3.1 γ Spectrometry Benches

Several γ -scanning benches are used in the facility. They measure fuel rod gamma activity. There are five of them.

- BASILIC, used for integral γ -scanning axial and radial distributions and specific peak measurements
- BANEX, DECROISSANT, and PIC LA for decay measurements during integral γ -scanning and specific peak measurements
- Capture U8, with respect to measuring the modified conversion rate

The detectors used are hyper pure Germanium diodes (HP-Ge), cooled with liquid nitrogen. These detectors enable fine resolution of peaks emitted by fission products.

Each bench has its own electronics, calibrated, steered, and qualified separately. However, these electronics are identical, in order to homogenize experimental tools (➤ [Fig. 51](#)).

■ Figure 51

View of gamma spectrometry benches used at EOLE and MINERVE

■ **Figure 52**
Schematic diagram of automatic changer

8.3.2 Automatic Changer

One of the large improvement works performed over the last few years was the creation of an automatic fuel rod changer called BASILIC, to replace the old system where rods were placed one by one under the measurement diode. It has numerous advantages which include the following:

- Fewer human risks during measurements.
- Risks of rod drops avoided.
- Time gained between two measurements.
- Minimized contact between researchers and fuel rods (reduced dosimetry).
- Optimized precision for the position of rods under the diode (► [Fig. 52](#)).

The changer comprises three main parts, shown in (► [Fig. 53](#)).

1. The rod storage unit, made up of two storage drums which can hold 20 rods each, placed on a tilting trolley to store rods in a reinforced tunnel
2. The rod extracting/inserting system, made up of a grappler arm and a conveyor to carry rods to the measurement line
3. The actual measurement line made up of a sideways moving trolley, the diode and γ shielding/collimation materials

8.3.3 Use of DSP

In the approach for improvement, control, and reduction of uncertainties and experimental optimization, the old analog measurement channels dedicated to gamma spectrometry were

■ **Figure 53**
View of the automatic changer

fully renovated to switch to the use of a digital channel. The Digital Signal Processor (DSP) stage replaces the amplifier-coder pair in the analog channel. It allows systematic errors linked to electronics downtime to be highly minimized thanks to certain advanced functions of the digital coder part, particularly the ability to take into account stacks during acquisition. At DSP output, two AIM multichannel analyzers allow the DSPs to be connected two at a time in the NIM racks and to connect them directly to the acquisition PC through an Ethernet connection (or USB), which greatly facilitates the synchronized control of the five measurement benches. They also help avoid compatibility problems with ISA buses, which are more and more frequent with new PCs.

The use of these DSPs on the five spectrometry channels either increases counting rates all while enabling correction of downtime to ensure measurement quality (the statistical uncertainty linked to counting itself is therefore highly diminished in the final result), or reduces measurement times thanks to its ability to process the strongest signal (➤ [Fig. 54](#)).

8.4 Fission Chambers

One of the historical activities of CEA/Cadarache is to design and manufacture neutron detectors called fission chambers (FC). These fission chambers are manufactured in a dedicated laboratory then used in nuclear reactor cores in France or abroad, with the aim to locally characterize the neutronic field (fluence rate, spectral indexes, etc.). This laboratory, which is one of a kind in Europe or even worldwide, has the ability to provide physicists with special detectors unavailable on the market, notably due to the nature of sensitive deposits made available (thorium, uranium, neptunium, plutonium, etc.). For example, the only one French manufacturer of fission chambers can only provide U^{235} detectors in its catalog.

■ **Figure 54**
Measurement system

These small detectors have the interest of obtaining local neutron flux measurements with precise positioning and a signal obtained and processed by the measurement channel, mainly due to neutrons.

Fission chambers are gas detectors where one of the two cylindrical electrodes is covered with a thin layer of fissile matter. In a neutron field, the nuclei of this deposit can “fission” and thus emit two very energetic fission products (160 MeV overall). They are emitted at 180° from one to the other: one of the two fission products is stopped in the deposit itself (or its base) and the other will ionize the gas (usually argon) contained in the detector. Charges are collected through the electrical field generated by the high voltage applied to the two electrodes.

The general characteristics of a fission chamber are:

- Bias voltage
- Gas pressure: 50–500 V, 5–20 bar
- Lining thickness $< 1 \text{ mg cm}^{-2}$

We therefore measure either pulses or a constant current if the number of fissions is high. This current increases with the bias voltage up to a $V_{\min}$ value where all electrons produced have been collected (before any recombination in the gas). This phenomenon, called chamber saturation, exists up to another voltage $V_{\max}$ at which point sufficiently energetic primary electrons will in turn ionize the gas. This saturation range (or saturation plateau) corresponds to the main operating zone of the sensor.

These fission chambers are generally manufactured in a glove box as shown in ► [Fig. 55](#).

The process used to assemble fission chambers is tungsten inert gas (TIG) or laser welding. Welding is performed in an argon atmosphere stabilized by a few rods in a sealed chamber placed in a glove box used for welding (► [Fig. 56](#)).

The standard models of assembled sensors are miniature cylindrical fission chambers with an outside diameter of 8, 4, and 1.5 mm. CEA can also design prototypes to meet a specific requirement (► [Figs. 57–59](#)).

It is therefore a live “in-core” measurement which requires the presence of a measurement channel (instrumentation tube to allow passage of the measuring rod). This fission chamber is connected to an electronic channel with a pre-amplifier, amplifier, and multichannel analyzer to obtain a pulse spectrum which is then processed (► [Fig. 60](#)).

8.5 Gamma Ionization Chambers

The gamma ionization chamber is associated with a 7-mm diameter cable, an electrometer with a PC outlet, and an acquisition software program for online recording.

■ Figure 60

Example of measurements obtained with these fission chambers. Fission spectrum of a ²⁴¹Pu-lined fission chamber

■ Figure 61

Gamma ionization chamber

These ionization chambers must be calibrated beforehand using a reference gamma source.

The chamber can be introduced into the reactor either in fixed or movable position through an automatic linear axial positioning device (positioner).

The gamma ionization chamber used is of 0.3 cm³ PTW semiflex type. Its outside diameter is 6.9 mm. Its sensitivity limit is 1.2 mGy min⁻¹ (☛ Fig. 61).

This ionization chamber was implemented during the ADAPh program in MINERVE in 2005 (see ☛ Sect. 5.6). It particularly enables the evolution of the delayed gamma population to be followed after a power transient.

8.6 Fissile and Activation Detectors

A case of ten activation detectors covering a wide range of use is available in the measurement room of the EOLE/MINERVE facility (► Fig. 62).

It allowed characterization of the flux by power unit ($2.5 \times 10^6 \text{ n cm}^{-2} \text{ s}^{-1} \text{ W}^{-1}$) and the neutron spectrum of the thermal thimble (measurement channel located in a graphite assembly, outside the driver zone) of MINERVE using the Cadmium ratio measurement ($R_{Cd} \approx 3$).

It is planned that this irradiation channel will be used to take capture cross-section measurements on actinides of interest, in particular, ^{238}U and ^{237}Np . The idea is to determine the Cadmium ratio of an isotope of interest, in relation to that of a reference isotope with a well-controlled section. An additional study carried out using other detectors, notably manganese, gold, aluminum-gold (0.1%), copper, tantalum, and cobalt helped assess those most well adapted to this type of study.

A device for centering and positioning dosimeters and calibration sources was also manufactured in order to reduce the uncertainty on the ability to reproduce the measurement (► Fig. 63).

Further to these preliminary studies, Cu-Mn (80%) and Al-Au (0.1%) “monitor” dosimeters in the form of 0.762 and 1 mm wires will be used, along with ^{238}U and ^{237}Np fissile detectors, in the form of encapsulated balls in a Vanadium capsule. It will first involve showing the feasibility of the thermal ($\sigma_{2,200}$) and epithermal (I_0) ^{238}U capture cross-section measurement, with an uncertainty below 5%. This measurement can then be extended to ^{237}Np and more generally, to any other isotope of interest (fissile or not) in the future.

8.7 Procedures Linked to the Oscillation Technique

8.7.1 Oscillator

It is a vertical electromechanical oscillator, controlled by a position servomechanism with the following main characteristics:

- Sinusoidal, square, or pseudo-square movement
- 0–900 mm course with selection of the average position
- Sinusoidal period: from 10 to 120 s
- Square or pseudo-square period: from 20 to 120 s
- Square transit time: 1 s
- Pseudo-square transit time: 5 s

It is controlled by a time base with a clock, which issues synchronization signals sent to the acquisition system (➤ [Fig. 64](#)).

8.7.2 The Automatic Pilot Rod

The MINERVE automatic pilot rod (see ➤ [Fig. 65](#)) is made up of a rotor and a stator covered with cadmium sections. Its total worth is several dozen pcm, and its differential worth is from

■ Figure 64
View of the MINERVE oscillator

■ **Figure 65**
MINERVE reactor automatic pilot rod with cadmium sections

■ **Figure 66**
Closed loop control between the pilot chamber and the automatic pilot rod

0.3 to 1 pcm per degree depending on the layout of absorbers and the position in the reflector. A capacitive sensor allows the rotor's rotation angle to be recorded (i.e., the coverage of cadmium sectors) in the form of analog voltage.

It is coupled with a CC5 type boron lined ionization chamber ("pilot chamber") placed in the reflector through a closed loop control channel (see ► Fig. 66) controlled by neutron flow variations.

This measurement assembly has a wide pass band (of approximately 10 Hz) and high performance in order to compensate for reactivity variations generated by the oscillation of samples. It allows reactivity variations to be measured with $10^{-8} \Delta k/k$ precision for a measurement period of approximately 1 h. It also ensures the criticality of the core by compensating for the slight reactivity disturbances caused by the oscillations.

The pilot rod underwent maintenance in 2002 (installation of a ball bearing and replacement of the rod). The pilot chamber connector technology was also reworked in 2003. It must however be noted that in order to extend programs, the pilot chamber and closed loop control channel will eventually need to be replaced by more modern systems.

■ Figure 67

Example of an acquisition signal during an oscillation measurement

8.7.3 Acquisition and Online Processing System for Oscillation Measurements

Oscillation experiments require the analysis of periodic signals presented in the form of analog voltages, images of phenomena.

Information (see ► Fig. 67) on the pilot chamber signal (in blue), the rotation angle of the pilot (in red), and the position of the oscillator (in yellow), are synchronized on the clock which controls the oscillator and are processed in real time by an acquisition system comprising a micro-computer and an acquisition card with analog-digital converters.

8.7.4 Active Sample Handling Equipment

Ventilated enclosure: A ventilated enclosure (see ► Fig. 68) is associated with the MINERVE and EOLE reactors. It contains:

- Two glove boxes for handling samples containing plutonium
- One shielded cell for handling fissile samples irradiated in power reactors, or more generally, active samples

It should be noted that the MINERVE facility currently does not have a neutron shielded cell.

The transfer container or “milk can”: A “milk can” container (see ► Fig. 69) is used to transfer irradiated or active samples from the shielded cell to the chimney of the MINERVE reactor.

A neutron shielded milk can is currently being studied in order to transfer Curium samples for the OSMOSE program (see ► Sect. 5.7) to the reactor.

8.7.5 Oscillation Samples

Sample Origin and Manufacturing

In general, samples studied until now in MINERVE can be classified according to two categories: irradiated (or fresh) fuel samples, and samples containing a specific dopant isotope.

■ Figure 68
Shielded cell for handling active samples

■ Figure 69
“Milk can” for transferring samples from the cell to the MINERVE reactor chimney

The general characteristics of previous and current samples are listed below. However, there is the possibility of changing these characteristics in the future, for example, to adapt to new types of fuels (HTR fuel rods for example).

- *Irradiated samples* are made up of a length of irradiated fuel rod from a light water power reactor (LWR) assembly, generally cut at the Cadarache Department of Fuel Studies. This length therefore includes both the irradiated fuel and the original cladding of the rod. It is approximately 95 mm long.
Two sealed Zircaloy four sheaths make up the outer casing of the sample. Their dimensions are adapted to those of the length of fuel.
The material balance of the irradiated fuel is known by dissolution of an adjacent length.

■ **Figure 70**
Example of fuel pellets for the OSMOSE program

■ **Figure 71**
OSMOSE oscillation sample

- *Samples containing a dopant isotope* are made up of fuel pellets containing the studied dopant isotopes, and two sealed Zircaloy four sheaths.

Fuel pellets (see example in ► [Fig. 70](#)) are manufactured by homogeneously mixing the dopant isotope in a matrix which can be either fissile (usually natural or depleted UO_2) or inert (Al_2O_3). The pellet column is approximately 95 mm long, and has a standard PWR diameter of approximately 8.1 mm. Pellet centering is generally favored in the case of a UO_2 matrix due to mechanical resistance, lack of humidity and mixture homogeneity. The dopant mass is determined using determining design calculations, and optimized so as to correspond with the linear operating range of the automatic pilot rod ($\sim \pm 10$ pcm). It should be noted that it is possible to create annular pellets to reduce the sample's reactivity if necessary.

In order to control the fuel's material balance, at least three control pellets are manufactured. Two of them are intended for analyses after dissolution. The third is preserved in case of inconsistency between the analyses of the first two.

The Zircaloy four sheaths generally have diameters of $\varnothing 8.36 \times 9.56$ mm, and $\varnothing 10.2 \times 10.6$ mm. The overall length of samples (see ► [Fig. 71](#)) is approximately 103.5 mm.

The sample manufacturer differs depending on the nature of the dopant isotope. An inert dopant can be used in a simple fume chamber or glove box, a radioactive isotope may require the much more cumbersome use of a shielded cell.

Sample Transport and Transfer

Transporting active samples (irradiated or containing gamma emitter actinides or neutrons for example) from their manufacturing location to the MINERVE, then from it to the MINERVE reactor, *has become a major issue* during recent experimental programs (HTC, CREDIT BURN UP, OSMOSE). It involves adapting to regulations in force and their changes, to available means, effective authorizations, regular maintenance and to the various constraints of the facilities involved.

Currently, the kinematics of samples is as follows:

$$\begin{array}{c} \text{manufacturer} \xrightarrow{\text{ad hoc flask}} \text{COMIR(CHICADA)} \xrightarrow{\text{IL30}} \text{INB MINERVE} \\ \xrightarrow{\text{milk can}} \text{MINERVE reactor.} \end{array}$$

To control the non-contamination and to transport active samples from their manufacturing location to COMIR hot laboratory (eventually replaced by CHICADE) requires a durable transport flask approved for the content of the samples. The RD15IIB should meet this requirement. An authorization extension is however required for any new types of content (for example, for all actinides containing OSMOSE samples).

Transporting samples from COMIR (CHICADE) to the MINERVE shielded cell requires:

- A durable transport flask approved for the content of samples
- That the shielded cell be equipped with docking compatible with the transport flask
- Zero contamination of samples (therefore, particularly a clean transport container)

Currently, the IL30 is used for transport between COMIR and MINERVE. This aging flask is currently the last existing able to adapt to the docking of the MINERVE shielded cell, however it will not last forever (it should also be noted that it cannot leave the Cadarache site). In addition, switching to PADIRAC type docking (adapted to the RD15IIB or equivalent) on the MINERVE shielded cell seems necessary in the long run.

Transferring the shielded cell to the MINERVE reactor plant is carried out using a “milk can.” It must be adapted to the type of radiation emitted by the sample (beta-gamma or neutrons).

9 Integral Parameter Determination Through Experiment

The physical measurements taken in a core modeled by a critical mock-up are used to qualify all or part of the core codes which will then be used in production. A full program is built according to the expectations in terms of qualification requirements, but also in terms of significant advances in measuring techniques (related precision and uncertainties). The variables of interest are called *integral parameters* (as opposed to differential measurements such as cross-sections), simply due to the fact that they are expressed as variables represented (mathematically) by integrals (on all or part of the space coordinates of the phases, notably energy).

The main parameters measured during an experimental campaign are the following:

- *The critical size* (through measuring the doubling time).
- *The reactivity effects*, that is to say the modification of the neutron balance in a particular configuration, due to inserting a particular heterogeneity (presence of absorbers, modification

of the geometry, aging of the fuel). When the reactivity variation is carried-out to another variation, it is referred to as *reactivity coefficients* (temperature coefficient, boron coefficient, etc.).

- The *axial and radial fission rate distributions* using the gamma scanning technique or using miniature fission chambers. In regular lattices, these measurements provide the material buckling.
- Power *renormalization* by specific peaks.
- The *spectral indexes* either by γ -scanning (for example, the modified conversion factor) or by using fission chambers.
- The *gamma doses*, which are a first step in determining gamma heating itself.
- The *delayed neutron fraction*, using neutron noise techniques.

For each type of measurement, the associated techniques are now generally outlined.

9.1 Critical Size

Critical size determination enables validation of different parts of a core calculation route:

- On a homogeneous lattice (one speaks about “regular” lattice), critical size gives information mainly either on nuclear data used by the code, the core (lattice) modeling being simplified, or on the self-shielding and leakage models for deterministic codes
- On a heterogeneous lattice (one speaks about “mock-up”), critical size enables validation of the calculation scheme in its totality, i.e., both nuclear data libraries and the numerical treatment of the Boltzman equation in the case of deterministic codes (self-shielding treatment, flux calculation by more sophisticated methods as Method of Characteristics, interface current in multicell, equivalence, etc.)

The critical size is fully characterized by:

- The number of rods loaded in the core
- The number of guide-tubes
- The temperature of the moderator
- The soluble boron concentration (if necessary)
- The residual reactivity of the core obtained by divergence and measurement of the doubling time
- The critical dimension of the pilot rod inserted into the core, in order to maintain power at a certain value
- The divergence date (mainly for MOX cores, due to the aging Pu)

The doubling time is systematically measured on EOLE during each approach. It is based on the monitoring of the neutron population of the core through the evolution of the counting rate of a calibrated fission chamber in the core. This monitoring is shown in  [Figs. 72–74](#).

The power increase is directly proportional to the neutron population increase, in such a way that the following can be written: $P(t) = P_0 \exp(\omega t)$ with $\omega \equiv \ln 2 / T_d$, T_d being the doubling time of the critical configuration in question.

■ Figure 72

Measurement of the counting rate rise during divergence and extraction of the doubling time

■ Figure 73

Example of Nordheim curve

The doubling time thus obtained is then inserted into the core's Nordheim equation, which provides the excess reactivity value (in delayed neutron fraction units – the pcm).

$$\rho_{\text{excess}} = \ell\omega + \beta - \sum_i \beta_i \frac{\lambda_i}{\omega + \lambda_i}, \quad (1)$$

■ Figure 74

Movement of samples during oscillations in MINERVE

where

- ℓ is the neutron generation time
- β is the effective fraction of delayed neutrons
- The λ_i and β_i are the partial decay and fraction constants of delayed neutrons in the delayed neutron i groups

The following figure shows the graphic representation of this evolution: (FUBILA/REF core).

9.1.1 Application of Critical Size Determination

This paragraph would formally belong to [Sect. 9.2](#). We will show how to use the critical parameters to deduce reactivity effects between to critical configurations. As we just mentioned, each critical configuration is fully determined by: the number and type of fuel rods and guide-tubes loaded, the boron concentration (if any), the temperature of the moderator and the excess reactivity ρ_{excess} deduced from the doubling time measurement by using the ad hoc Nordheim curve (for MOX core, one will add the date as complementary information). We will take the case of the isothermal temperature coefficient (ITC) for the sake of simplicity.

The ITC is formerly defined by the reactivity variation versus temperature between one (critical) state “ i ” and another denoted “ j ,” through the relationship: $\alpha = (\Delta\rho/\Delta T)_{i,j}$.

The reactivity variation can be covered by an increase or decrease of boron in the moderator, so that the ITC is expressed as

$$\alpha = \left(\frac{\Delta\rho}{\Delta T} \right)_{i,j} = \frac{\rho_{excess,i}(T_i, B_i) - \rho_{excess,j}(T_j, B_j)}{T_i - T_j} + \frac{C_{B,i} - C_{B,j}}{T_i - T_j} \left(\frac{\Delta\rho}{\Delta C_B} \right)_{i,j} \quad (2)$$

and becomes, without boron:

$$\alpha = \left(\frac{\Delta \rho}{\Delta T} \right)_{i,j} = \frac{\rho_{excess,i}(T_i) - \rho_{excess,j}(T_j)}{T_i - T_j}. \quad (3)$$

As one can see, the divergence approach needs to keep the configuration parameters (except temperature) constant in order to deduce a consistent coefficient. The difficulty arising in this approach is to recover a wide range of temperature variations by using the same critical size, in particular in the presence of boron or if the ITC value is high between two temperatures. The subcritical approach to this measurement is developed in [Sect. 9.2.8](#).

9.2 Reactivity Effect Measurements

Reactivity effect measurements are one of the most important parameters measured in the experimental reactors. Their precision involves many parameters and as many different techniques.

Various common techniques are described hereafter to measure reactivity effect measurements in critical to slightly subcritical lattices. The problem of ADS subcriticality determination, that is an absolute measure, will not be described here.

One will focus on three main techniques used:

- Inverse kinetics, for dynamic measurements
- Amplified and/or modified source methods (ASM and MSM) for quasi static measurements
- Sample oscillation technique

The first one is an absolute measurement, as the two other ones are relative measurements. They are based on the use of miniature fission chambers whose count rate is analyzed to unfold the reactivity effect.

9.2.1 Reactivity Worth Measurement by Inverse Kinetics

Reactivity effect measurement by inverse kinetics is a dynamic method based on online monitoring of counting during the experiment. It can be applied to a wide range of reactivity measurements without significant restrictions. On the one hand, it uses gross rod drop measurements of various rods and on the other hand, the time analysis of these files using an equation resolution Point Reactor approximation kinetics program. As a reminder, this equation is given by the following expression (1):

$$\begin{aligned} \frac{\rho(t)}{\beta} = & \frac{\Lambda}{\beta} \frac{\dot{C}(t)}{C(t)} + 1 - \frac{C_0}{C(t)} \sum_k \alpha_k \exp(-\lambda_k t) - \frac{\varepsilon}{\beta C(t)} \sum_k \dot{\zeta}_{0k} \exp(-\lambda_k t) \\ & - \frac{1}{C(t)} \sum_k \alpha_k \lambda_k \int_0^t C(t') \exp(-\lambda_k(t-t')) dt' - \frac{s\varepsilon}{\beta C(t)}, \end{aligned} \quad (4)$$

where notations are standard. In particular, ε represents the fission chamber detection efficiency. This last equation is discretized for numerical resolution. Three major contributions can be pointed out:

- Prompt neutrons:

$$\frac{\Lambda}{\beta} \frac{\dot{C}(t)}{C(t)}. \quad (5a)$$

- The source term

$$\frac{s\varepsilon}{\beta C(t)}. \quad (5b)$$

- Delayed neutrons

$$1 - \frac{C_0}{C(t)} \sum_k \alpha_k \exp(-\lambda_k t) - \frac{\varepsilon}{\beta C(t)} \sum_k \zeta_{0k} \exp(-\lambda_k t) - \frac{1}{C(t)} \sum_k \alpha_k \lambda_k \int_0^t C(t') \exp(-\lambda_k(t-t')) dt'. \quad (5c)$$

The discretized form of (4) is the following:

$$\rho_s(n) = 1 + \frac{\Lambda}{\beta\theta} \times \frac{W_{n+1} - W_n}{W_n} - \frac{1}{W_n} \times \sum_{j=1}^6 \alpha_j W_0 \exp(-\lambda_j t_n) - \sum_{j=1}^6 \alpha_j (1 - \exp(-\lambda_j \theta)) \sum_{p=1}^{n-1} \frac{W_p}{W_n} \exp(\lambda_j(t_p - t_n)) - \frac{\Lambda S_e}{\beta W_n}, \quad (6)$$

where

- $\rho_s(n)$ is the reactivity at time step “ n ”
- θ is the sampling time (typically 0.4 s)
- n is the current time (step)
- W_n is the power at time step “ n ”
- S_e is the intrinsic effective source seen by the detector
- The other notations have their usual significations

This statistical uncertainty increases with “ n ” because the counting decreases with time and because the reactivity at n depends on all reactivity measured at previous times. One evaluates this statistical uncertainty to range between ± 0.5 and 1.0%.

However, one must take into account the systematic uncertainties due to the kinetics parameters themselves which are calculated values. One evaluates the systematic uncertainty on the pilot rod reactivity due to each parameter to be:

- ℓ (Prompt neutron generation time): $< \pm 0.5\%$
- β : $< \pm 0.2\%$
- (α_j, λ_j) : $\sim \pm 5\%$

The associated statistical uncertainty on the reactivity measured by rod drop is small (less than 1%). The method is very sensitive to the effective source term S_e which must be determined with special care; the reactivity does not depend strongly on the prompt neutron lifetime and on the β_{eff} . The precision on (α_j, λ_j) is the dominant source of uncertainty.

The rod drop technique can be used with confidence for reactivity worths up to few delayed neutron fractions.

9.2.2 Reactivity Effects by Subcritical Measurements

9.2.3 Principle of Subcritical Measurements

The interest of subcritical measurements is to provide an additional value of a reactivity effect or reactivity coefficient by avoiding an analysis of two critical states for which either the number of rods or the soluble boron variation between the two states are to be taken into account as a bias in the calculation.

They help determine the reactivity effect of a local or overall disturbance (of any kind) using a critically measured reactivity standard (generally, the reactivity weight of the pilot rod measured with the rod drop technique). Just as for determining the critical size, these subcritical measurements of a reactivity effect allow libraries and/or calculation schemes of the pattern in question (regular or mock-up) to be qualified. These measurements apply just as well to the effects of an isolated absorber or a cluster of absorbers as to a temperature or soluble boron concentration variation. They are used to obtain an effect value in addition to that obtained by critical size measurement. They require counting rates of fission chambers arranged in the core.

The reactivity effects of a disturbance of any kind (absorber, solution boron, fuel substitution or temperature coefficient, etc.) are determined from counts carried out subcritically in a so-called disturbed configuration, and then compared with counts carried out in a so-called “reference” configuration. The subcritical measurements are carried out using fission chambers ($\varnothing = 8$ mm, with a high fissile mass content) arranged in several areas of the core at the mid-height plane. This determination of the reactivity is a relative method requiring the knowledge of a reactivity standard, which is generally the reactivity weight of the pilot rod, also measured, generally using the rod drop technique described in [Sect. 9.2.1](#).

9.2.4 Amplified Source Method (ASM)

The ASM method is based on the use of the occasional kinetic model, for which the steady state caused by a source (effective or external) is established. The equations, given irrespective of time, governing the system are the following:

$$\begin{cases} 0 = \frac{(\rho - \beta_{eff})}{\Lambda} \bar{N} + \sum_{i=1}^6 \lambda_i \bar{C}_i + S_{eff}, \\ 0 = \frac{\beta_{i,eff}}{\Lambda} \bar{N} + \lambda_i \bar{C}_i, \quad i = 1, \dots, 6 \end{cases} \quad (7a)$$

with $\bar{N}$ the effective population of neutrons in the core

$$\bar{N} = \left\langle \phi^*, \frac{1}{v} \Phi \right\rangle \quad (7b)$$

$\bar{C}_i$ the effective concentration of the i family of precursors

S_{eff} the effective outside source

λ_i the decay constant of the i family of precursors

ρ the core's reactivity

Λ the prompt neutron generation time

$$\Lambda = \frac{\langle \phi^*, \frac{1}{\nu} \Phi \rangle}{\langle \phi^*, F\Phi \rangle}. \quad (7c)$$

In steady-state operating conditions, time is not a factor; the average $\bar{N}$ population of the core depends only on the source used and the negative reactivity inserted. Therefore,

$$\rho = -\frac{\Lambda S_{eff}}{\bar{N}}. \quad (8)$$

By inserting the reaction rate in the detector, defined by $R = \langle \Sigma_d, \Phi \rangle$, the following is obtained by multiplying the top and bottom of (8) with the previous notations (7b) and (7c):

$$\rho = -\frac{S_{eff}}{R} \frac{\langle \Sigma_d, \Phi \rangle}{\langle \phi^*, F\Phi \rangle}, \quad (9)$$

where

S_{eff} is the effective outside source,

R is the reaction rate

Σ_d is the diffusion factor

Φ represents the flux (subcritical) in the reactor

ϕ^* is the adjoint flux in the critical reactor associated with the real reactor (it is a function of weighting, chosen as being the adjoint for the sake of convenience)

F is the multiplication operator by fission

With the approximations of the monokinetic point reactor, where the flux can be broken down into a function of time only $n(t)$ and a function of the other space coordinates of the phases $\psi(\mathbf{r}, E)$, the latter relationship is, more generally, written as follows:

$$\rho = -\frac{\varepsilon S_{eff}}{R}, \quad (10)$$

where

$$\varepsilon = \frac{\langle \Sigma_d, \Psi \rangle}{\langle \phi^*, F\Psi \rangle}, \quad (11)$$

where ψ is the shape factor of the subcritical flux, depending on $\vec{r}$ and E , and stemming from the decomposition of the flux (depending on time) as in $\Phi(t, \vec{r}, E) = n(t) \Psi(\vec{r}, E)$. When the system is stationary, the subcritical flux is identified with the shape factor: $\Phi(\vec{r}, E) = \Psi(\vec{r}, E)$.

The relationships (10) and (11) show that the negative reactivity of a configuration is inversely proportional to the counting rate R of the detector if one assumes that ε and S_{eff} are constant. As the latter variables cannot be measured (only calculated), it is difficult, or even impossible, to associate them with any uncertainties. Therefore, the absolute measurement of reactivity is not possible with this method. However, it is possible to use it through another method using a reactivity taken as a reference standard.

If one knows the negative reactivity ρ_0 of a reference state which corresponds to a reaction rate measured in the detector R_0 , ρ_1 is deduced corresponding to the reaction rate R_1 through the following simple relationship:

$$\rho_1 = \frac{R_0}{R_1} \rho_0. \quad (12)$$

The negative reactivity measured through the ASM method is simply deduced from the relationship of two reaction rates (which in practice is reduced to two counting rates).

The validity assumptions of the kinetic-point model expressed (ϵ and S_{eff} considered as constants) require however, that the reactivity measured be low enough for the shape factor $\Psi(\vec{r}, E)$ to not only be modified locally, and for the detector to be considered as located outside the disturbed area.

When the reactivity variation due to a disturbance is too high to avoid spatial and energetic effects at the detector, a calculation correction is required. This correction is called MSM, which is described in the following section.

9.2.5 Modified Source Multiplication (MSM) Method

The corrective parameters to be applied to the detector's response stem from calculations of disturbances carried out on the various configurations of the studied core.

The starting equation is the source inhomogeneous transport equation

$$(F - L)\Phi = S, \quad (13)$$

where

F is the fission production operator

L is the decay operator (transfers, leaks, various absorptions, etc.)

S is the source term

This equation corresponds with two other sourceless relationships (direct and adjoint) without source corresponding to the related critical system:

$$\begin{cases} (\lambda F - L)\phi(\vec{r}, E) = 0, \\ (\lambda F^* - L^*)\phi^*(\vec{r}, E) = 0, \end{cases} \quad (14)$$

where $\lambda - 1/k_{eff}$, $\phi(\vec{r}, E)$ and $\phi^*(\vec{r}, E)$ are respectively the direct and adjoint fluxes of the critical state, F^* and L^* are respectively the adjoint operators of F and L .

Scalar products are used to write the following by multiplying (13) by $\phi^*(\vec{r}, E)$ and by integrating on the space of the phases:

$$\rho = -\frac{\langle \phi^*, S \rangle}{\langle \phi^*, F\Phi \rangle}. \quad (15)$$

By inserting the detector's response into the latter relationship, the following expression is obtained:

$$\begin{aligned} \rho &= -\frac{\langle \phi^*, S \rangle}{\langle \phi^*, F\Phi \rangle} \times \frac{R}{R} = -\langle \phi^*, S \rangle \frac{\langle \Sigma_d, \Phi \rangle}{\langle \phi^*, F\Phi \rangle} \times \frac{1}{\langle \Sigma_d, \Phi \rangle} \\ &= -\epsilon \frac{S_{eff}}{R}, \end{aligned} \quad (16)$$

where

$$\epsilon \equiv \frac{\langle \Sigma_d, \Phi \rangle}{\langle \phi^*, F\Phi \rangle} \quad (17)$$

and

$$S_{eff} = \langle \phi^*, S \rangle. \quad (18)$$

The definition of the detector's worth shows that it depends on both the position of the detector in the core (in relation to the disturbance) and, of course, the nature of the detector through the intermediary of Σ_d . The worth takes into account the disturbances induced near the detector through the shape factor $\Phi(\vec{r}, E)$.

In addition, the effective source depends mainly on the critical adjoint flux $\varphi^*(\vec{r}, E)$ and on the type of source used, S .

The reactivity can only give reactivity variation relative values, for the same reasons as the ASM method. For a reactivity standard (in "0" state), (16) is rewritten as:

$$\rho_1 = \underbrace{\frac{R_0}{R_1} \rho_0}_{\text{"ASM" value}} \times \underbrace{\frac{\varepsilon_1}{\varepsilon_0} \frac{S_{eff,1}}{S_{eff,0}}}_{\text{MSM correction}} \quad (19)$$

the term $(\varepsilon_1/\varepsilon_0) (S_{eff,1}/S_{eff,0})$ takes into account the variation of the detector's worth and the effective source between the two compared states. These variables are calculated through the transport code.

The corrections used should allow any reactivity variation to be determined, regardless of its amplitude or the position of the detector. The corrective factor can be broken down into several terms.

Either the index m corresponding to the *measurement* (reaction rates in the detectors), or the c index corresponding to the *calculation* (detector worths and the source term)

Equation (19) can be rewritten

$$\frac{\rho_1(\vec{r})}{\rho_0(\vec{r})} = \frac{R_{m,0}(\vec{r})}{R_{m,1}(\vec{r})} \times \frac{\varepsilon_1(\vec{r})}{\varepsilon_0(\vec{r})} \frac{S_{eff,1}}{S_{eff,0}}, \quad (20)$$

where

$$\varepsilon_i(\vec{r}) = \frac{\langle \Sigma_d, \Phi_i \rangle}{\langle \phi_i^*, F \Phi_i \rangle} = \frac{R_{c,i}(\vec{r})}{I_{F,i}} \quad i = 0, 1 \quad (21)$$

with $I_{F,i} \equiv \langle \varphi^*, F \Phi_i \rangle$ the fission normalization integral (for the i configuration)

This therefore gives,

$$\frac{\rho_1(\vec{r})}{\rho_0(\vec{r})} = f_{MSM}(\vec{r}) \times \frac{R_{m,0}(\vec{r})}{R_{m,1}(\vec{r})} \quad (22)$$

with

$$f_{MSM}(\vec{r}) \equiv \left(\frac{S_{eff,1}}{\langle \phi_1^*, F \Phi_1 \rangle} \right) / \left(\frac{S_{eff,0}}{\langle \phi_0^*, F \Phi_0 \rangle} \right) \times \frac{R_{c,1}(\vec{r})}{R_{c,0}(\vec{r})}. \quad (23)$$

This MSM corrective factor appears as a correlation factor between the detector's position and the inferred reactivity value, knowing the standard. When the MSM factor is equal to the unit, determination of the reactivity becomes independent from the position of the fission chamber. The flux's shape factor remains constant between the two states (low disturbance, the asymptotic rate is quickly established), as well as the effective source, and the kinetic point model applies. The results from the ASM technique are found.

9.2.6 Practical Implementation of ASM and MSM Subcritical Measurements

The subcritical measurement technique, based on amplification of the source, is based on the premise that the counting rates of fission chambers arranged in and around the core are proportional in terms of subcriticality in the core, according to the following relationship:

$$C = \frac{RCaFa}{\rho} \times \varepsilon_{MSM}, \quad (24)$$

where

- C is the counting rate in the chamber
- ρ is the subcriticality level
- $RCaFa$ is a proportionality factor (*Reactivity Calibration Factor*)
- ε_{MSM} is the “MSM” factor described in the previous paragraph

The $RcaFa$ factor is obtained by using the reactivity value of the pilot rod measured by inverse kinetics (rod drop). This factor is given by the following relationship:

$$RCaFa = \frac{\Delta\rho^{PR}}{\left(\frac{\varepsilon}{C_{PRd}} - \frac{1}{C_{PRu}}\right)} \quad (25)$$

with

$\Delta\rho^{PR}$ being the pilot rod efficiency, measured by rod drop,

$1/C$ is the inverse of the count rate

PRu corresponds to the pilot rod in raised position (out from the core)

PRd corresponds to the pilot rod in lowered position (down)

ε is the MSM factor between PRu and PRd configuration (generally equal to 1 since the PR worth is about several tens of β_{eff})

The overall reactivity effect is calculated as:

$$\Delta\rho = \underbrace{\left(\frac{\varepsilon_{MSM}}{C_{Pert.}} - \frac{1}{C_{Ref.}}\right) \times RCaFa}_{\text{direct term}} + \underbrace{\frac{\delta\rho}{\delta T} \cdot (T^{Ref.} - T^{Pert.}) + \frac{\delta\rho}{\delta t} \cdot (t^{Ref.} - t^{Pert.}) + \frac{\delta\rho}{\delta CB} \cdot (CB^{Ref.} - CB^{Pert.})}_{\text{correction terms}} \quad (26)$$

relationship where

$1/C$ is the inverse of the count rate

$Ref.$ represents the reference condition

$Pert.$ represents the disturbed condition

$RCaFa$ is a calibration factor of the count rate on the pilot rod worth (*Reactivity Calibration factor*)

T is the temperature

t is the date of the measurement. This must be taken into account in the case of MOX cores where Pu aging cannot be negligible)

$\delta\rho/\delta T$ is the ITC

$\delta\rho/\delta t$ is the plutonium aging

$\delta\rho/\delta CB$ is the boron worth coefficient

ε_{MSM} is what is called modified source multiplication (MSM) factor between the reference configuration and the disturbed one

9.2.7 Associated Uncertainties

The uncertainty on the ASM reactivity coefficient is deduced from the error propagation law.

$$\sigma(\Delta\rho)^2 = \sum_i \left(\frac{\partial\Delta\rho}{\partial x_i} \right)^2 \sigma(x_i)^2 + 2 \sum_{i=1}^{n-1} \sum_{j=i+1}^n \left(\frac{\partial\Delta\rho}{\partial x_i} \right) \left(\frac{\partial\Delta\rho}{\partial x_j} \right) \text{cov}(x_i, x_j), \quad (27)$$

where the x_i are all the variables contained in (26).

For the general purpose, we will consider that all the variables are independent, so the correlation term in (27) can be neglected.

After some trivial algebra, the final variance of the reactivity worth in subcritical measurement is given by the expression:

$$\begin{aligned} & \left[\frac{\sigma(\Delta\rho)}{\Delta\rho} \right]^2 \\ &= \underbrace{\left[\frac{RCaFa \times \left(\frac{\varepsilon_{MSM}}{C_{pert}} - \frac{1}{C_{ref}} \right)}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(RCaFa)}{RCaFa} \right)^2 + \frac{\left(\frac{\sigma(\varepsilon_{MSM})}{C_{pert}} \right)^2 + \left(\frac{\varepsilon_{MSM}\sigma(C_{pert})}{C_{pert}^2} \right)^2 + \left(\frac{\sigma(C_{ref})}{C_{ref}^2} \right)^2}{\left[\frac{1}{C_{ref}} - \frac{\varepsilon}{C_{pert}} \right]^2}}_{\text{countings}} \right. \\ &+ \underbrace{\left[\frac{\frac{\delta\rho}{\delta T} \times (T^{ref} - T^{pert})}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta T)}{\delta\rho/\delta T} \right)^2 + \frac{\sigma(T^{ref})^2 + \sigma(T^{pert})^2}{(T^{ref} - T^{pert})^2}}_{\text{temperature}} \right. \\ &+ \underbrace{\left[\frac{\frac{\delta\rho}{\delta t} \times (t^{ref} - t^{pert})}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta t)}{\delta\rho/\delta t} \right)^2 + \frac{\sigma(t^{ref})^2 + \sigma(t^{pert})^2}{(t^{ref} - t^{pert})^2}}_{\text{Pu decay}} \right. \\ &+ \underbrace{\left[\frac{\frac{\delta\rho}{\delta CB} \times (CB^{ref} - CB^{pert})}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta CB)}{\delta\rho/\delta CB} \right)^2 + \frac{\sigma(CB^{ref})^2 + \sigma(CB^{pert})^2}{(CB^{ref} - CB^{pert})^2}}_{\text{boron concentration}} \right], \quad (28a) \end{aligned}$$

where

$$\left[\frac{\sigma(RCaFa)}{RCaFa} \right]^2 = \left[\left(\frac{\sigma(\Delta\rho_{RodDrop})}{\Delta\rho_{RodDrop}} \right)^2 + \frac{\left(\frac{\varepsilon_{MSM}}{C_{PRd}} \right)^2 + \left(\frac{\varepsilon_{MSM}\sigma(C_{PRd})}{C_{PRd}^2} \right)^2 + \left(\frac{\sigma(C_{PRUp})}{C_{PRUp}^2} \right)^2}{\left[\frac{\varepsilon_{MSM}}{C_{PRd}} - \frac{1}{C_{PRUp}} \right]^2} \right]. \quad (28b)$$

In the particular case where no MSM correction is taken into account, $\varepsilon_{MSM} = 1$ (the reactivity effect is small enough to neglect the local flux disturbance), the two last expressions can be rewritten as, remembering that $\sigma(C) = \sqrt{C}$

$$\begin{aligned} \left[\frac{\sigma(\Delta\rho)}{\Delta\rho} \right]^2 = & \left[\frac{RCaFa \times \left(\frac{1}{C_{pert}} - \frac{1}{C_{ref}} \right)}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(RCaFa)}{RCaFa} \right)^2 + \frac{\left(\frac{1}{C_{pert}} \right)^3 + \left(\frac{1}{C_{ref}} \right)^3}{\left[\frac{1}{C_{ref}} - \frac{1}{C_{pert}} \right]^2} \right] \\ & + \left[\frac{\frac{\delta\rho}{\delta T} \times (T^{ref} - T^{pert})}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta T)}{\delta\rho/\delta T} \right)^2 + \frac{\sigma(T^{ref})^2 - \sigma(T^{pert})^2}{(T^{ref} - T^{pert})^2} \right] \\ & + \left[\frac{\frac{\delta\rho}{\delta t} \times (t^{ref} - t^{pert})}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta t)}{\delta\rho/\delta t} \right)^2 + \frac{\sigma(t^{ref})^2 - \sigma(t^{pert})^2}{(t^{ref} - t^{pert})^2} \right] \\ & + \left[\frac{\frac{\delta\rho}{\delta CB} \times (CB^{ref} - CB^{pert})}{\Delta\rho} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta CB)}{\delta\rho/\delta CB} \right)^2 + \frac{\sigma(CB^{ref})^2 - \sigma(CB^{pert})^2}{(CB^{ref} - CB^{pert})^2} \right] \end{aligned} \quad (29a)$$

with

$$\left[\frac{\sigma(RCaFa)}{RCaFa} \right]^2 = \left[\left(\frac{\sigma(\Delta\rho_{RodDrop})}{\Delta\rho_{RodDrop}} \right)^2 + \frac{\left(\frac{1}{C_{PRd}} \right)^3 + \left(\frac{1}{C_{PRUp}} \right)^3}{\left[\frac{1}{C_{PRd}} - \frac{1}{C_{PRUp}} \right]^2} \right]. \quad (29b)$$

In general $\sigma(\Delta\rho_{RodDrop}) \sim 5.1\%$ is the dominant term of the uncertainty formula. Since it arises from the nuclear data used for the rod drop analysis, it is not reducible and represents the lower uncertainty value attainable with this method.

9.2.8 Example: Isothermal Temperature Coefficient (ITC)

The temperature coefficient will be given by the expression $(\Delta\rho/\Delta T)_{i,j} = \Delta\rho_{ASM}/T_i - T_j$ where $\Delta\rho_{ASM}$ does not contain the temperature dependence, as in (26) (since it is the coefficient we look for).

The uncertainty of the reactivity worth in subcritical measurement is found by propagating the individual variances through error propagation law. The final variance is given by the expression:

$$\delta^2 \left(\frac{\Delta\rho}{\Delta T_{i,j}} \right)_{ASM} = \frac{1}{(T_i - T_j)^2} \left[\delta^2(\Delta\rho_{ASM}) + \frac{2(\Delta\rho_{ASM})^2}{(T_i - T_j)^2} \delta^2(T_i) \right], \quad (30)$$

where

$$\left[\frac{\sigma(\Delta\rho_{ASM})}{\Delta\rho_{ASM}} \right]^2$$

$$\begin{aligned}
&= \underbrace{\left[\frac{RCaFa \times \left(\frac{\varepsilon_{MSM}}{C_{pert}} - \frac{1}{C_{ref}} \right)}{\Delta\rho_{ASM}} \right]^2 \times \left[\left(\frac{\sigma(RCaFa)}{RCaFa} \right)^2 + \frac{\left(\frac{\sigma(\varepsilon_{MSM})}{C_{pert}} \right)^2 + \left(\frac{\varepsilon_{MSM} \sigma(C_{pert})}{C_{pert}^2} \right)^2 + \left(\frac{\sigma(C_{ref})}{C_{ref}^2} \right)^2}{\left[\frac{1}{C_{ref}} - \frac{\varepsilon}{C_{pert}} \right]^2}}_{\text{countings}} \right. \\
&\quad + \underbrace{\left[\frac{\frac{\delta\rho}{\delta t} \times (t^{ref} - t^{pert})}{\Delta\rho_{ASM}} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta t)}{\delta\rho/\delta t} \right)^2 + \frac{\sigma(t^{ref})^2 + \sigma(t^{pert})^2}{(t^{ref} - t^{pert})^2}}_{\text{Pu decay}} \right. \\
&\quad \left. \left. + \underbrace{\left[\frac{\frac{\delta\rho}{\delta CB} \times (CB^{ref} - CB^{pert})}{\Delta\rho_{ASM}} \right]^2 \times \left[\left(\frac{\sigma(\delta\rho/\delta CB)}{\delta\rho/\delta CB} \right)^2 + \frac{\sigma(CB^{ref})^2 + \sigma(CB^{pert})^2}{(CB^{ref} - CB^{pert})^2} \right]}_{\text{boron concentration}} \right] \right. \quad (31)
\end{aligned}$$

These equations can be used, for example, in parallel to equations of  Sect. 9.1 for the critical determination of the reactivity coefficient.

9.2.9 Reactivity Effect Measurements by Sample Oscillation

Principle

The experimental oscillation technique is used to measure small reactivity variations. The interest of oscillations stems from the fact that neutron measurements can be carried out using very small quantities of materials, for example, a single fuel element or a small sample of a few grams of the body or isotope studied.

When a small zone at the center of a reactor is made to undergo a periodic disturbance, for example, capture or fission type, the neutron density disturbance can be separated into two components.

The first, irrespective of the position, is called overall disturbance, and is expressed in the following way:

$$\frac{dn}{dt} = H \frac{dk}{k}, \quad (32)$$

where H is the reactor's transfer function and dk/k is the reactivity variation.

The second component, in phase with the disturbance, quickly diminishes when one moves away from the disturbed zone and is called local disturbance. This measurement is used for experiments based on the method of the equivalent sample; the signal is therefore obtained by fission chambers surrounding the oscillation rod. It can be shown that by disregarding the terms due to transfers, the overall disturbance can be expressed as follows:

$$\frac{dn}{dt} = AH\delta\Sigma_a + BH\delta\Sigma_f, \quad (33)$$

where $A\delta\Sigma_a + B\delta\Sigma_f$ represents the reactivity variation.

The overall signal can be measured anywhere in the reactor far enough away from the disturbance. Rather than measure the neutron density variation (as was the case on the UKAEA DIMPLE reactor), for MINERVE, it is preferred that the reactivity effect of the studied sample

be compensated using an automatic pilot rod (see ► Sect. 8.7.2) especially designed to respond quickly to small reactivity variations (~ 10 pcm). In the past, other reactors (MARIUS, CESAR, and MASURCA) were also equipped with such a system.

Practical Implementation

The technique consists in oscillating studied samples at the center of the experimental lattice, with the aim of measuring the reactivity variation associated with an uncertainty linked to the less than 1% reproducibility of the experiment. Each sample is placed in an oscillation rod and is moved vertically from time to time between two positions located in the mid-height plane and outside the experimental zone (see ► Fig. 62).

The signal of the upper axle (containing the studied sample) is compared with the signal of the lower axle (containing a reference sample) of the oscillation rod (see ► Fig. 62). The reactivity effect difference of the two samples then allows the effect of the upper and lower axles to be avoided. Each sample is measured five times in order to identify any systematic biases and to reduce the standard deviation on the measurement average. One measurement consists of 20 oscillations lasting 60 s each, or ten oscillations lasting 120 s each.

The flux variation resulting from the oscillation is detected by a boron-lined fission chamber called pilot chamber, placed outside the driver zone and connected to an automatic pilot rod made up of a stator and rotor covered with cadmium sections: the relatively significant covering provokes a reactivity variation which can reach approximately ± 20 pcm. The connection between the rotation angle of the rod and the reactivity is determined experimentally using calibration samples with various ^{235}U enrichments and various ^{10}B contents, whose reactivity is known at better than 1% through deterministic calculations.

By quadratically accumulating the uncertainties linked to the reproducibility of measurements ($\sim 1\%$), to the material balance of samples ($\sim 1\text{--}2\%$) and to the calibration of the automatic pilot rod ($\sim 2\%$), the final uncertainty on reactivity is approximately 3% at 1σ .

The average amplitude of the automatic pilot rod's signal is determined for each oscillation cycle. The comparison of amplitudes of each cycle for a single measurement gives information on the repeatability of the experiment. The comparison of the average amplitude of five measurements of a single sample gives information on the reproducibility of measurements. The average amplitude for all the measurements of a single sample is therefore compared with that of calibration samples in order to determine the reactivity effect of the studied sample.

The experimental values are generally interpreted through an exact disturbance calculation. The reactivity effects of studied samples are generally used in the calculation for the reactivity effect of ^{235}U and boron through calibration samples.

Calibration of the Automatic Pilot Rod

Calibration of the automatic pilot rod (see description in ► Sect. 8.7.2) takes place in two phases:

- Determination of the pilot rod's negative reactivity curve
- Determination of the pilot rod's differential calibration curve

1. Negative reactivity curve of the automatic pilot rod

This phase has the following objectives:

- To check the correct operating and proper centering of the automatic pilot rod. It involves making sure that the overlapping of cadmium sections does in fact vary when the pilot rod's rotation angle is influenced from the control rack, and therefore that

■ **Figure 75**
Pilot rod negative reactivity curve during HTC-MOX program in R1-MOX

the position control operates properly and that the rotor's movement is not restricted (mechanical seizure for example).

- To make sure that the automatic pilot rod is capable of compensating reactivity variations ranging between $[-10 \text{ pcm}; +10 \text{ pcm}]$.
By designing oscillation samples, the reactivity variation caused by oscillation is in absolute value, less than or equal to 10 pcm.
- To define an operating range on which the issued signal/negative reactivity relationship is bijective.

Indeed, two signals can potentially correspond to a single deployed cadmium surface and therefore the same negative reactivity, as shown in ➤ [Fig. 63](#).

In practice, the measurement is carried out in the following way:

- Positioning of the rotor at a given angle (i.e., a given signal (*copy voltage*))
- Divergence of the reactor all rods raised and determination of the core's excess reactivity using the measurement of the doubling time and the Nordheim curve

The example of the negative reactivity curve of the automatic pilot rod obtained during the HTC-MOX program in the R1-MOX configuration of the MINERVE reactor is shown in ➤ [Fig. 75](#).

The rotor was taken to its maximum rotation angles, corresponding to the copy voltages -14 V and $+13 \text{ V}$. Beyond these extremes, the automatic pilot rod is no longer able to compensate: this is referred to as pilot rod stalling.

It is observed that a bijective relationship between the copy voltage and negative reactivity is only possible on the range $[-14 \text{ V}; +4 \text{ V}]$ or on the range $[+4 \text{ V}; +13 \text{ V}]$ and that only the first range guarantees the ability to compensate reactivity effects of $\pm 10 \text{ pcm}$.

2. Differential worth curve of the automatic pilot rod

(a) Principle

The purpose of the differential worth curve is to determine an operating point within the operating range chosen in accordance with *point 1*.

■ Figure 76

Illustration of the reference angle on a standard oscillation signal

This operating point corresponds to a given copy voltage and therefore to a reference rotation angle which will be noted θ_0 . In practice, it will represent the average ideal value of the signal obtained during sample oscillation. ➤ Figure 76 depicts this point.

With

θ_{raised} = average maximum angle obtained during oscillation of a given sample, corresponding to a given position of the oscillator (raised or lowered to a stop)

θ_{low} = average minimum angle obtained during oscillation of a given sample, corresponding to the other given position of the oscillator (lowered or lowered to a stop)

θ_{avg} = average angle = $(\theta_{\text{raised}} + 2\theta_{\text{low}})/2$. $\theta_{\text{avg}} \neq \theta_0$ must be followed

It is recalled that the purpose of oscillation measurements is to compare amplitudes ($\theta_{\text{raised}} - \theta_{\text{low}}$) obtained using various studied samples.

(b) Experimental implementation

Experimentally, the measurement is carried out by positioning the automatic pilot rod at various angles, i.e., at various copy voltages, in the determined operating range using the negative reactivity curve (see point 1).

For each copy voltage, at the BFX point of the closed loop control (see ➤ Sect. 8.7.2) (that is to say downstream of the pilot chamber and upstream of the automatic pilot rod), an outside test signal (simulating a neutron flux disturbance) is inserted in the form of low amplitude voltage (at approximately 0.1 V in absolute value), and in each case the signal's amplitude and average position is recorded.

The differential calibration curve of the automatic pilot rod is therefore recreated, as given in the example in ➤ Fig. 77.

It can be shown that on a certain operating range, this curve can be written in the following way:

$$f = f(\theta) = \frac{1}{\alpha\theta + \beta} \quad (34)$$

■ **Figure 77**

Example of the differential calibration curve

or otherwise written as

$$f(\theta_0) = f(\theta) \times (1 - C_B \times (\theta - \theta_0)) \quad (35)$$

with

θ_0 = the reference angle to be determined and which will be worked around for all oscillations

θ = average angle for a given measurement, such as $\theta \neq \theta_0$

$f(\theta)$ = experimentally obtained amplitude for a given measurement

$f(\theta_0)$ = the amplitude which would have been obtained if it had been possible to perfectly experimentally adjust θ such as $\theta = \theta_0$

θ_0 is therefore chosen toward the middle of this range, while making sure that a reactivity variation of ± 10 pcm around this position is possible without stalling the pilot rod and so that θ_0 is part of the operating range determined in ► Sect. 3.1.

C_B is directly deduced from the value of α , β , and θ_0 through the relationship $C_B = -1/\theta_0 + \beta/\alpha$.

Statistical processing through linear regression enables the uncertainty on coefficients on the right, and therefore on C_B to be determined, while taking into accounts both uncertainties on the average signal and on the amplitude.

Signal Calibration

Once the automatic pilot rod is calibrated, the signal issued by the pilot rod must be calibrated. To do so, two series of calibration samples are used. One consists of UO_2 samples with various

■ **Figure 78**
Calibration curve with borated samples

^{235}U enrichments (0.25, 0.5, 0.72, 1, 2, 3, 4, and 4.95%). The other is made up of UO_2 matrix samples mixed with boron with various contents (0, 60, 100, 150, 200, 333, 400, 419, 500, and 1,062 ppm). ➤ [Figures 78](#) and ➤ [79](#) give examples of calibration curves obtained in R1-UO₂ during the HTC program.

The reactivity of these samples is also calculated using deterministic calculation codes, with an uncertainty, linked to the knowledge of nuclear data on ^{235}U and boron, of approximately 1% (1σ). Thus, the reactivity of any samples oscillated in MINERVE can be determined by simple comparison of its response to that of calibration samples.

The total uncertainty on calibration measurements, taking into account uncertainties on the material balance of samples, the reproducibility of measurements, and the uncertainty on their calculated reactivity weights, is approximately 2% (1σ).

9.3 Measurement of Fission Rate Distributions

Fission rate distributions are measured using two complementary techniques: fission chambers and integral gamma spectrometry.

They have several advantages: for regular cores (axially and/or radially), the distribution of fission rates allows the flux curve to be determined and thus identify the “fundamental” parameters such as the material buckling. This material buckling is then used either as input data to qualify the calculation of the cell in an infinite environment, or compared with the buckling calculated for the cell at $k_{\text{eff}} = 1$. Axially, it also allows the core calculation scheme to be qualified (regular or mock-up lattice) by imposing axial leaks, radially, it conditions the critical size calculation.

In “homogeneous” cores, the axial and radial distributions also enable the *reflector gain* calculation to be qualified. This will be developed further on.

■ Figure 79

Calibration curve with U-235 samples

9.3.1 Distributions by Fission Chambers

Distributions by fission chambers are accomplished by inserting a miniature fission chamber ($\varnothing 4$ mm) into a sealed over-cladding, in replacement of a fuel rod. Measurements are taken in critical conditions.

As opposed to gamma spectrometry, they help highlight the spectrum effects in distributions using fission chambers of different types:

- Fissile isotopes for the thermal field
- Fertile isotopes for the highest energies

These spectrum effects, characterized by “spectral indexes,” are covered in ► [Sect. 9.4](#).

Radial Measurements

Radial measurements are carried out in the core’s mid-height plane in order to avoid the axial curve of the fission rate distribution. The counting rates for the chamber are renormalized on a chamber calibrated in the core, which follows the power variation during measurement. When the measurement is completed, the chamber is moved to another position.

Axial Measurements

Axial measurements are carried out using the linear positioner allowing the chamber in question to be inserted at various heights in the core. The counting rate of the chamber is renormalized in the same way as for the radial measurement.

As opposed to gamma spectrometry measurements, distribution measurement by fission chambers allows us to go beyond the fissile column, in the reflector, and to validate the reflector gain calculation.

The uncertainties on axial and radial distributions by fission chambers are less than or around 1% at 1σ .

9.3.2 Distributions by Integral Gamma Spectrometry

Integral spectrometry is based on the measurement of the total gamma activity of a fuel rod after irradiation. This measurement allows the total fission rate in the rod to be traced. For the same type of fuel (MOX or UO_2), the total activity is directly proportional to the fission rate, through emitter fission products. Measurement of this γ activity is carried out between 550 keV (beyond the Compton front) and up to 2,500–3,000 keV.

As the activity depends greatly on fission products and their lifetime, it must be normalized at a decay “standard,” which is a fuel of the same nature, measured continuously.

The integral γ spectrometry technique is used for:

- Radial measurements
- Axial measurements

These two measurements are slightly different in the way the final result is normalized, however the renormalization principle for decay is identical (► [Figs. 80](#) and ► [81](#)).

Radial Measurements

For radial measurements, counts are carried out at the core’s mid-height plane, where the fission rate axial distribution is the most level, which allows any curve correction whatsoever to be avoided. The advantage of the γ -scanning technique is completely clear here: it is possible to create fission rate maps on a large number of rods in a minimum amount of time. The number of

■ Figure 80

Gamma spectrometry measurement on EOLE/MINERVE critical mock-ups. Insertion of UO_2 or MOX fuel rods under a germanium diode

■ Figure 81

Gamma spectrometry measurement on EOLE/MINERVE critical mock-ups. Example of taking into account the dead time on fission product spectrums

rods generally measured is often around a hundred, broken down into several individual maps with twenty rods. Each individual map is the subject of a dedicated measurement.

Rods are counted several times (runs) on the measurement channel in order to reduce the associated statistical uncertainty. The analysis is carried out as follows.

Where $T_{i,k}$ is the count rate γ of an individual rod i at k run, the renormalized fission rate is given by:

$$T_{i,k} = \frac{C_{i,k} - R_i}{C_{M,k} - R_M}, \quad (36)$$

where

$C_{i,k}$ is the count rate of the rod i at k run

R_i is the measurement of the residual activity of the rod i (counted once)

$C_{M,k}$ is the count rate of the monitor rod M at k passage

R_M is the residual activity of the same monitor M

The statistical uncertainty on this count rate is given by the well-known propagation law, and leads to:

$$\begin{aligned} (\Delta T_{i,k})^2 = & \left(\frac{\partial T_{i,k}}{\partial C_{i,k}} \right)^2 (\Delta C_{i,k})^2 + \left(\frac{\partial T_{i,k}}{\partial R_i} \right)^2 (\Delta R_i)^2 + \left(\frac{\partial T_{i,k}}{\partial C_{M,k}} \right)^2 (\Delta C_{M,k})^2 \\ & + \left(\frac{\partial T_{i,k}}{\partial R_M} \right)^2 (\Delta R_M)^2 \end{aligned} \quad (37)$$

with

$$(\Delta C_{i,k})^2 = C_{i,k},$$

$$(\Delta R_i)^2 = R_i,$$

$$(\Delta C_{M,k})^2 = C_{M,k}, \quad (38a)$$

$$(\Delta R_M)^2 = R_M,$$

$$\left(\frac{\partial T_{i,k}}{\partial C_{i,k}} \right)^2 = \left(\frac{\partial T_{i,k}}{\partial R_i} \right)^2 = \frac{1}{(C_{M,k} - R_M)^2}, \quad (38b)$$

$$\left(\frac{\partial T_{i,k}}{\partial C_{M,k}} \right)^2 = \left(\frac{\partial T_{i,k}}{\partial R_M} \right)^2 = \frac{(C_{i,k} - R_i)^2}{(C_{M,k} - R_M)^4}. \quad (38c)$$

We suppose here that the counts are independent from each other so that there is no correlation between the runs or the rods.

Performing some algebra and reorganizing leads to the following relationship, in terms of relative uncertainties:

$$\left(\frac{\Delta T_{i,k}}{T_{i,k}} \right)^2 \equiv \delta T_{i,k}^2 = \frac{C_{i,k} + D_{i,k}}{(C_{i,k} - D_{i,k})^2} + \frac{C_M + D_M}{(C_M - D_M)^2}. \quad (39)$$

The average value of each individual rod after the three runs is then the combination of these individual uncertainties. So, the following is obtained:

$$\bar{T}_i = \frac{\sum_k T_{i,k} / (\delta T_{i,k})^2}{\sum_k 1 / (\delta T_{i,k})^2} \quad (40)$$

with a relative statistical uncertainty given by

$$\delta \bar{T}_i = \sqrt{\frac{1}{\sum_k 1 / (\delta T_{i,k})^2}}. \quad (41)$$

As usual, the more the number of measurements is, the less the associated uncertainty on the average value will be.

Once the individual uncertainties are calculated for each run, an average value is calculated as the weighted average of the chosen fuel rods. Once individual counts are completed, each fission rate is then renormalized on a set value (generally the average value of the fission rate of a few fuel rods). This allows a full γ -scanning map to be created by mixing several separate normalized measurements on the same fuel rods.

The average A is calculated as

$$A = \frac{1}{N} \sum_{i=1}^N T_i, \quad (42)$$

where N is the number of weighting fuel rods. The associated uncertainty is given by

$$\delta A = \frac{1}{N} \sqrt{\sum_{i=1}^N (T_i)^2}. \quad (43)$$

Each new fuel rod now has the value

$$\tilde{T}_i = \bar{T}_i / A. \quad (44)$$

The associated uncertainty will be the quadratic combination of both statistical and weighting terms:

$$\delta \tilde{T}_i = \sqrt{(\delta \bar{T}_i)^2 + (\delta A)^2}. \quad (45)$$

Axial Measurements

Axial γ -scanning is very similar to the radial γ -scanning process. It differs among other things by the opening of the measurement window in order to integrate the γ activity on a smaller part of the fuel. Here, the axial variation of the curve must be highlighted. The fissile height is subdivided into units measured from the bottom of the rod up to the top of the rod. Once the measurements are completed, the curve obtained over the maximum is renormalized.

Uncertainties on axial or radial distributions by γ -scanning are approximately 1–1.5% (at 1σ).

9.3.3 Particular Use of Fission Rate Distributions: The Buckling Estimation

The buckling can be deduced from axial and radial distributions, in the case of homogeneous cores, with both fission chambers and integral gamma spectrometry. The processing of the buckling is based on a fit of the fission rates using a cosine or Bessel function of the first kind which is the eigenfunction of the axial or radial Helmholtz equation respectively.

For an axial fit for example, the function $a \cos(\sqrt{B^2}z + c)$ is adjusted on the set of experimental points using a descending Newton algorithm. Several calculations are carried out using various z value thresholds in order to estimate the best z range fitting the data (to avoid discrepancies due to thermal flux increases in the upper and in the lower part of the core).

The uncertainty on the three adjusted parameters (a, B^2, c) comes from error propagation using the Monte Carlo method. The convergence of the standard deviation for a set of points is checked by looking at its variation and figure of merit (FOM) versus history number (generally 1,000 history per threshold value is enough). Standard deviations of the fission rate at each z coordinate are estimated using error propagation on measured and monitor rods and then fission rates are sampled until calculation convergence.

The B^2 value to be retained (matching a given z threshold) is a compromise between a reduced chi-square χ_R^2 per degree of freedom as close to one as possible (checked to be less than a unilateral 5% risk threshold) and an uncertainty on B^2 as low as possible. The first criterion tends to reduce the z data range whereas the second tends to enlarge this range.

The statistical weighted average and the reduced uncertainty are obtained using the following formulae.

$$\overline{B_z^2} = \frac{\sum_{i=1}^n (B_z^2)_i / \sigma_i^2}{\sum_{i=1}^n 1 / \sigma_i^2} \quad \text{and} \quad \overline{\sigma_z^2} = \frac{1}{\sum_{i=1}^n 1 / \sigma_i^2}. \quad (46)$$

9.3.4 Determination of the Reflector Saving

The buckling values obtained enable one to extract the axial reflector saving δ_z of the core; for example. Knowing that, for a cylindrical core, the axial buckling is defined by

$$B_z^2 = \left(\frac{\pi}{H_{ext}} \right)^2 = \left(\frac{\pi}{H + 2\delta_z} \right)^2 \quad (47)$$

with H being the core fissile height, considered in first approximation without uncertainty.

The uncertainties are calculated as:

$$\Delta H_{ext} = \left(\frac{\pi}{B_z^2} \right) \Delta B_z \quad \text{or} \quad \Delta \delta_z = \frac{1}{2} \left(\frac{\pi}{B_z^2} \right) \Delta B_z. \quad (48)$$

9.3.5 Adjustment of Fission Maps by Particular Peaks

The renormalization of fission rate distributions between fuel rods of different types is of great interest for the physics of advanced cores where we mix both UO_2 and MOX assemblies, or between fuels of the same type but with very different fissile vectors. This adjustment is due to the normalization technique for integral γ -scanning maps on a decaying rod. The latter has a pseudo decay period that makes it impossible to mix two rods of different types on one map. Therefore, an absolute standard must be used, which is the formation rate of a fission product common to both types. Its contribution to the qualification of the calculation scheme is not direct; it is only done through the total renormalized fission rate distribution map.

Principle of Peak Check Technique

The purpose of the adjustment is to determine the relationship $[(\text{Fuel}_1 \text{ fission rate})/(\text{Fuel}_2 \text{ fission rate})]$ It is carried out as follows:

$$\left[\frac{F_{\text{Fuel}_1}}{F_{\text{Fuel}_2}} \right]_{\text{Exp}} = \left[\frac{FP_{\text{Fuel}_1}}{FP_{\text{Fuel}_2}} \right]_{\text{Exp}} \times \left[\frac{r_{\text{Fuel}_2}}{r_{\text{Fuel}_1}} \right]_{\text{Cal}}, \quad (49)$$

where

- F_{Fuel_1} and F_{Fuel_2} are the fission rates measured in rods 1 and 2, respectively
- FP_{Fuel_1} and FP_{Fuel_2} are the quantities measured for a particular fission product of interest
- r_{Fuel_1} and r_{Fuel_2} are calculated correction factors (average fission yields)

The latter are expressed as:

$$r_i^{Fuel_1} = \sum_{k=1}^L \left(\tau_k \times y_k^i \right)_{fast}^{Fuel_1} + \left(\tau_k \times y_k^i \right)_{thermal}^{Fuel_1} \quad \text{is the average fission yield in the type 1 rod} \quad (50a)$$

and

$$r_i^{Fuel_2} = \sum_{k=1}^L \left(\tau_k \times y_k^i \right)_{fast}^{Fuel_2} + \left(\tau_k \times y_k^i \right)_{thermal}^{Fuel_2} \quad \text{is the average fission yield in the type 2 rod} \quad (50b)$$

with

$$\sum_{k=1}^L (\tau_k)_{fast}^{Fuel_1} + (\tau_k)_{thermal}^{Fuel_1} = \sum_{k=1}^L (\tau_k)_{fast}^{Fuel_2} + (\tau_k)_{thermal}^{Fuel_2} = 1, \quad (50c)$$

where

- y_k^i is the cumulated fission yield of the fission product i for the fissile isotope k
- τ_k is the fission rate of the fissile isotope k
- L is the number of fissile nuclei contained in the fuel

with a gap between the thermal and fast ranges in order to properly take into account the fission yields.

The commonly used fission product is ^{140}Ba , even though other FPs can also be analyzed, as for example ^{92}Sr . ^{140}Ba is a fission product with a very high cumulated fission yield whose direct descendent, ^{140}La , has several particularities which make it a good candidate for the particular peak measurement:

- High intensity and high energy (1,596 keV) γ line, not disturbed by the Compton front
- A relatively long decay period enabling low residual activity postirradiation measurements

The formation reaction of ^{140}La is as follows:

It can be shown that the total fission rate emitted in the fuel rod is given by the following expression:

$$F = \left\langle \frac{F_{\text{La}}}{Y_{\text{Ba}}} \right\rangle = \frac{C_{\text{La}}(\lambda_{\text{La}} - \lambda E)}{I_\gamma Y_{\text{La}} f_{\text{La}} \times \left[\frac{\lambda_{\text{La}}}{\lambda_{\text{Ba}}} e^{-\lambda_{\text{Ba}} T_0} (1 - e^{-\lambda_{\text{Ba}} I}) (1 - e^{-\lambda_{\text{Ba}} T_c}) - \frac{\lambda_{\text{Ba}}}{\lambda_{\text{La}}} e^{-\lambda_{\text{La}} T_0} (1 - e^{-\lambda_{\text{La}} I}) (1 - e^{-\lambda_{\text{La}} T_c}) \right]} \times \frac{T_c}{T_a}, \quad (51)$$

where

- $Y_{\text{Ba}} = \sum_j (Y_{j,th} \tau_{j,th} + Y_{j,F} \tau_{j,F})_{\text{Ba}}$
- $Y_{j,th}$ is the thermal fission yield of the ^{140}Ba (^{140}La) for the isotope j
- $\tau_{j,th}$ is the thermal fission relationship of the isotope j in the fuel at the total fission rate
- $Y_{j,F}$ is the fast fission yield of the ^{140}Ba (^{140}La) for the isotope j
- $\tau_{j,F}$ is the fast fission relationship of the isotope j in the fuel at the total fission rate
- F is the overall fission rate in the fuel

- F_{Ba} is the production rate of the ^{140}Ba $F_{Ba} = F \times Y_{Ba}$
- C_{La} is the integral of the peak at 1,596 keV of the ^{140}La
- I is the irradiation time
- T_0 is the cooling time for the rod, that is to say the amount of time between the end of irradiation and the start of the measurement
- T_c corresponds to the measuring time
- f_{La} is the self-absorption factor of the gamma in the fuel, that is to say its probability of being detected without being absorbed. It is deduced from a photonic propagation calculation using the Monte-Carlo MCNP code precisely modeling the fuel rod and the measuring bench with the associated detectors
- I_γ is the intensity of the gamma line detected

$\lambda_{Ba}(\ln(2)/T_{Ba} = 6.2971 \times 10^{-7} \text{ s}^{-1}$, with $T_{Ba} = 12.74 \text{ h} (\pm 1.2 \text{ h i.e., } 0.39\%)$ for the ^{140}Ba and $\lambda_{La}(\ln(2)/T_{La} = 4.7812 \times 10^{-6} \text{ s}^{-1}$, with $T_{La} = 40.27 \text{ h} (\pm 25.2 \text{ s i.e., } 0.02\%)$ for the ^{140}La are the decay constants of the two fission products.

Associated Uncertainties

The wide majority of uncertainty on the readjustment factor stems from the calculation of average yields. This uncertainty has two distinct sources:

- Basic nuclear data (fission yields), for which the uncertainties are known through assessed datasheets
- The calculated values (fission rates), for which the uncertainties are generally estimated. Firstly, they are considered equal to uncertainties a priori of fission integrals of isotopes taken into account in the calculation

One can consider that irradiation time, cooling time and count time are error free with regard to other sources of uncertainties. Usually, one postulates that dead time correction of a multi-channel analyzer should be perfect if dead time does not exceed 30–40%. With the new electronics (DSP, Digital Signal Processing) and associated research and investigation on its behavior versus dead time, one can precisely estimate the numerical correction brought by the lattice. Measurements show that the lattice is capable of reproducing integral and particular peak count rates at less than 1% precision up to dead times exceeding 50%. The uncertainty on this parameter will be considered as negligible with respect to the others sources. They are:

- Standard error on the net peak area C , equal to $\sqrt{C}$ if we assume that the count rates follow a Poisson law and that the background count rate under the peak remains negligible.
- Precision on nuclear data (decay constants, cumulated fission yields, etc.).
- Precision on calculated data used for the data unfolding (mainly the fission rates and the γ self-absorption factor).

The propagated uncertainty on the fission rate is directly connected to the error propagation law, taking into account the previous parameters. Two different partial derivatives will appear in the equations. The application of the error-propagation law leads to:

$$\left(\frac{\Delta F}{F}\right)_{La} = \sqrt{\left(\frac{\Delta C_{La}}{C_{La}}\right)^2 + \left(\frac{\Delta Y_{Ba}}{Y_{Ba}}\right)^2 + \left(\frac{\Delta f_{La}}{f_{La}}\right)^2 + \chi_{La}^2 (\Delta \lambda_{La})^2 + \chi_{Ba}^2 (\Delta \lambda_{Ba})^2} \quad (52)$$

with

$$\frac{\Delta C_{La}}{C_{La}} = \frac{1}{\sqrt{C_{La}}} \quad (53a)$$

$(\Delta f_{La}/f_{La})^2$ is the propagated uncertainty on the self-absorption factor, $(\Delta Y_{Ba}/Y_{Ba})^2$ is the uncertainty due to nuclear data (yield) and

$$\chi_{La}^2 = \left(\frac{1}{F} \frac{\partial F}{\partial \lambda_{La}} \right)^2 \quad \text{and} \quad \chi_{Ba}^2 = \left(\frac{1}{F} \frac{\partial F}{\partial \lambda_{Ba}} \right)^2. \quad (53b,c)$$

Performing some algebra leads to the following relationships:

$$\chi_{La}^2 = \left\{ \frac{1}{\lambda_{La} - \lambda_{Ba}} - \left[\begin{array}{l} \frac{e^{-\lambda_{Ba} T_0}}{\lambda_{Ba}} (1 - e^{-\lambda_{Ba} I}) (1 - e^{-\lambda_{Ba} T_c}) \\ + \frac{\lambda_{Ba}}{\lambda_{La}} \left(T_0 + \frac{1}{\lambda_{La}} \right) e^{-\lambda_{La} T_0} (1 - e^{-\lambda_{La} I}) (1 - e^{-\lambda_{La} T_c}) \\ - \frac{\lambda_{Ba} I}{\lambda_{La}} e^{-\lambda_{La} T_0} e^{-\lambda_{La} I} (1 - e^{-\lambda_{La} T_c}) \\ - \frac{\lambda_{Ba} T_c}{\lambda_{La}} e^{-\lambda_{La} T_0} e^{-\lambda_{La} T_c} (1 - e^{-\lambda_{La} I}) \end{array} \right] \right\} \left/ \left[\frac{C_{La} (\lambda_{La} - \lambda_{Ba}) T_c}{F \times Y_{Ba} \times f_{La} \times T_a} \right] \right\}^2 \quad (54)$$

for the derivation versus the ^{140}La variables
and

$$\chi_{Ba}^2 = \left\{ \frac{1}{\lambda_{La} - \lambda_{Ba}} - \left[\begin{array}{l} \frac{e^{-\lambda_{La} T_0}}{\lambda_{La}} (1 - e^{-\lambda_{La} I}) (1 - e^{-\lambda_{La} T_c}) \\ + \frac{\lambda_{La}}{\lambda_{Ba}} \left(T_0 + \frac{1}{\lambda_{Ba}} \right) e^{-\lambda_{Ba} T_0} (1 - e^{-\lambda_{Ba} I}) (1 - e^{-\lambda_{Ba} T_c}) \\ - \frac{\lambda_{La} I}{\lambda_{Ba}} e^{-\lambda_{Ba} T_0} e^{-\lambda_{Ba} I} (1 - e^{-\lambda_{Ba} T_c}) \\ - \frac{\lambda_{La} T_c}{\lambda_{Ba}} e^{-\lambda_{Ba} T_0} e^{-\lambda_{Ba} T_c} (1 - e^{-\lambda_{Ba} I}) \end{array} \right] \right\} \left/ \left[\frac{C_{La} (\lambda_{La} - \lambda_{Ba}) T_c}{F \times Y_{Ba} \times f_{La} \times T_a} \right] \right\}^2 \quad (55)$$

for the derivation versus the ^{140}Ba variables.

Classically, the count integral C is higher than 40,000 counts, leading to a statistical uncertainty of less than 0.5%. The self-absorption factor can be obtained with an uncertainty of less than 0.3% if an adequate convergence criterion (statistical – Monte Carlo – uncertainty on the tally in the detector) is selected. On the basis of an irradiation time of 1 h, and a cooling time of several days, with count rates of about 1–2 h, the relative uncertainty due to the $\chi_{La \times \Delta \lambda_{La}}$ term is lower than 0.001% and lower than 0.02% for the $\chi_{Ba \times \Delta \lambda_{Ba}}$ term.

The propagation of all sources of uncertainty generates an overall uncertainty on the adjustment factor of the ^{140}La of approximately 1.5%, which, combined with the overall uncertainty on radial maps by integral γ -scanning, gives an uncertainty on the renormalized map of approximately 2–2.5% (at 1σ).

9.4 Spectral Indexes

The spectral indexes allow the characterization of an energetic distribution of neutrons in the core. They are mainly measured in very well characterized spectrums such as regular lattices,

though they can also be measured in mock-up type configurations. Calculation of a spectral index in simplified geometry enables *qualification of nuclear data* associated with the calculation scheme in a given energetic range.

The standard measurement is carried out using miniature fission chambers (with a diameter of 4 mm) inserted into the core in mid-height position, although the use of activation foils allowed good results to be obtained in UOX configurations with removable rods in previous programs. These detectors are planned for future programs.

Roughly, one hundred fission chambers of various types (fissile or fertile, with a diameter of $\varnothing$ 1.5, 4, 8 or 10 mm) are available at EOLE, which can be used to characterize the spectrum at an area in the core.

By taking the five following chambers as examples:

- ^{235}U
- ^{238}U
- ^{239}Pu
- ^{242}Pu
- ^{237}Np

the following spectral indexes, among other things, can be deduced:

- $\sigma f^{238}\text{U}/\sigma f^{235}\text{U}$
- $\sigma f^{239}\text{Pu}/\sigma f^{235}\text{U}$
- $\sigma f^{237}\text{Np}/\sigma f^{239}\text{Pu}$
- $\sigma f^{242}\text{Pu}/\sigma f^{239}\text{Pu}$

and all the other possible variants.

9.4.1 Basic Principle

The general expression of a spectral index of an isotope “a” as compared to an isotope “r” is:

$$\frac{\bar{\sigma}_a}{\bar{\sigma}_r} = \frac{C_a/C_r}{(C_a/C_r)_c} \left(\frac{N_a^c}{N_a} \frac{\sigma_a^c}{\sigma_r^c} + \sum_{i \neq a} \frac{N_i^c}{N_a} \frac{\sigma_i^c}{\sigma_r^c} \right) - \sum_{i \neq a} \frac{N_i}{N_a} \frac{\bar{\sigma}_i}{\bar{\sigma}_r}, \quad (56)$$

where

- C_a/C_r is the relationship of count rates of the chamber “a” as compared to chamber “r”
- $(C_a/C_r)_c$ is the same relationship in a reference spectrum (for example, in a thermal column)
- N_a^c/N_a represents the case where the isotope “a” decreased since the measurement in the reference spectrum (particularly Pu-238 and Pu-241),
- σ_a^c/σ_r^c is the relationship of cross-sections averaged in the reference spectrum
- $\sum_{i \neq a} (N_i^c/N_a) (\sigma_i^c/\sigma_r^c)$ represents the contributions of impurities in the reference spectrum
- $\sum_{i \neq a} (N_i/N_a) (\bar{\sigma}_i/\bar{\sigma}_r)$ represents the contributions of impurities during measurement

By using the expressions $S = (\bar{\sigma}_a/\bar{\sigma}_r)\sigma_{a,c} = (\sigma_a^c/\sigma_r^c)\sigma_{i,c} = (\sigma_i^c/\sigma_r^c)\sigma_i = \bar{\sigma}_i/\bar{\sigma}_r$ and $C = (C_a/C_r)/(C_a/C_r)\varepsilon_a = (N_a^c/N_a)\varepsilon_{i,c} = (N_i^c/N_a)\varepsilon_i = N_i/N_a$ the spectral index, S, is re-written:

$$S = C(\varepsilon_a\sigma_{a,c} + \varepsilon_{i,c}\sigma_{i,c}) - \varepsilon_i\sigma_i. \quad (57)$$

The associated uncertainties depend greatly on the type of chamber used. They vary from 2% to nearly 10% for fertile fission chambers (^{238}Pu or ^{242}Pu lined).

Some Examples

1. Pu-239/U-235 spectral index

Pu-239/U-235 becomes the simplest case with both chambers assumed to be isotopically pure. In this case, the general expression reduces to:

$$\frac{\bar{\sigma}_9}{\bar{\sigma}_5} = \frac{C_9/C_5}{(C_9/C_5)_c} \frac{\sigma_9^c}{\sigma_5^c}. \quad (58)$$

Defining the spectral index as $S = \bar{\sigma}_9/\bar{\sigma}_5$ and $C = (C_9/C_5)/(C_9/C_5)_c$ and the ratio of the cross-sections as $\sigma = \sigma_9^c/\sigma_5^c$, the uncertainties in this case are expressed as:

$$\left(\frac{\Delta S}{S}\right)^2 = \left(\frac{\Delta C}{C}\right)^2 + \left(\frac{\Delta \sigma}{\sigma}\right)^2. \quad (59)$$

2. Np-237/Pu-239

In the Np-237 chamber, there can be no thermal column calibration, so the spectral index must be derived from calibrations in a fast spectrum. In this case, the count-rate ratio in the spectrum of interest is:

$$\frac{C_a}{C_r} = \frac{k_a \left(N_a \bar{\sigma}_a + \sum_{i \neq a} N_i \bar{\sigma}_i \right)}{k_r N_r \bar{\sigma}_r}, \quad (60)$$

where k is the efficiency of the chambers.

Replacing the kN products by the effective masses yields the following relationship for the general spectral index

$$\frac{\bar{\sigma}_a}{\bar{\sigma}_r} = \frac{M_r}{M_a} x \frac{A_a}{A_r} (C_a/C_r) - \sum_{i \neq a} \frac{N_i}{N_a} \frac{\bar{\sigma}_i}{\bar{\sigma}_r}. \quad (61)$$

For the Np-237 chamber, $N_i = 0$, therefore:

$$\frac{\bar{\sigma}_a}{\bar{\sigma}_r} = \frac{M_r}{M_a} x \frac{A_a}{A_r} x \frac{C_a}{C_r}, \quad (62)$$

where M_r , M_a are the effective masses and A_r , A_a are the atomic masses (239 and 237, respectively).

The uncertainty is simply calculated from the following:

$$\left(\frac{\Delta S}{S}\right)^2 = \left(\frac{\Delta C}{C}\right)^2 + \left(\frac{\Delta m}{m}\right)^2. \quad (63)$$

9.4.2 Modified Conversion Factor

The modified conversion factor is a spectral index, but is particular in the sense that it does not use fission chambers but relies on the particular peak spectrometry technique.

The modified conversion factor is defined as the ratio of ^{238}U radiative captures on total fission rate in the fuel rod. It is mainly used in the MOX fuel rods.

$$\text{Modified conversion factor} = \frac{^{238}\text{U captures}}{\text{total fissions}} = \frac{C8}{F_{\text{total}}}. \quad (64)$$

This definition is broader than that found in an all UO_2 core where the denominator is mainly the ^{235}U fission rate. This measurement is a postirradiation measurement directly on fuel rods.

The measurement is based on the detection of gamma peaks of two fission products: ^{143}Ce at 293.27 keV and ^{140}Ba at 537.31 keV, as well as ^{239}Np at 277.60 keV which characterizes the capture rate of the ^{238}U through the reaction

This measurement requires the detection of low energy gamma rays, which requires the use of a high efficiency diode. The ^{140}La peak at 1,596 keV is used as power normalization. It is shown that the modified conversion rate is given by the following expressions:

$$C8 = \frac{(\lambda_{\text{U9}} - \lambda_{\text{Np}}) \times N_{\text{Np}}}{g_{\text{Np}} \times \eta_{\text{Np}} \times f_{\text{Np}} \times \frac{\lambda_{\text{U9}}}{\lambda_{\text{Np}}} \times (1 - e^{-\lambda_{\text{Np}} t_e}) \times e^{-\lambda_{\text{Np}} t_c} \times (1 - e^{-\lambda_{\text{Np}} t_m})}, \quad (65)$$

for capture

$$F = \frac{\lambda_p \times C_{FP}}{Y_{FP} \times I_{FP} \times \eta_{FP} \times f_{FP} \times (1 - e^{-\lambda_p t_e}) \times e^{-\lambda_p t_c} \times (1 - e^{-\lambda_p t_m})} \quad (66)$$

for fission, which gives the final relationship for the modified conversion rate:

$$\frac{C8}{F} = \frac{\lambda_{\text{U9}} - \lambda_{\text{Np}}}{\lambda_p} \times \frac{\lambda_{\text{Np}}}{\lambda_{\text{U9}}} \times \frac{C_{\text{Np}}}{C_{FP}} \times Y_{FP} \times \frac{I_{FP}}{I_{\text{Np}}} \times \frac{\eta_{FP}}{\eta_{\text{Np}}} \times \frac{f_{FP}}{f_{\text{Np}}} \times \frac{(1 - e^{-\lambda_p t_e}) \times e^{-\lambda_p t_c} \times (1 - e^{-\lambda_p t_m})}{(1 - e^{-\lambda_{\text{Np}} t_e}) \times e^{-\lambda_{\text{Np}} t_c} \times (1 - e^{-\lambda_{\text{Np}} t_m})}, \quad (67)$$

where the notations are similar to the particular peak:

- F_p is the analyzed fission product
- λ_i is the decay constant of the nuclide i
- C is the integral count of the gamma peak of interest
- I_i is the probability of emission of the nuclide i gamma line
- f_i is the self-absorption factor of the gamma line
- η_i is the worth of the detector used
- t_e, t_c, t_m the irradiation, cooling and counting time

and $Y_{FP} = \sum_i (Y_{iT} \times \alpha_{iT} + Y_{iF} \times \alpha_{iF})$ is the effective fission yield of the fission product, calculated as for the peak check.

The self-absorption of gamma in the fuel is calculated in the same way as in the case of the measurement of the particular peak. The uncertainty associated with the modified conversion rate measured is approximately 2% (at 1σ).

These two last equations is rewritten in a slightly different form as:

$$C_8 = \frac{A(E_c)}{I_\gamma(E_c)R^P(E_c)T(E_c)}, \quad (68)$$

$$F = \frac{A(E_f)}{YI_\gamma(E_f)R^P(E_f)T(E_f)}, \quad (69)$$

where

$I_\gamma(E)$ is γ -ray emission probability of the reaction product with the energy E

$R^P(E)$ is the detection efficiency for a point source with the energy E

$T(E)$ is the efficiency transfer correction

Y is the average fission yield over all fissionable isotopes

$A(E)$ is the saturated count rate of the gamma-ray with the energy E

The saturated count rate $A(E)$ is obtained from net peak area measurements using the following relationship:

$$A(E) = \frac{N(E)}{t_r} C_\theta C_{dec} \quad (70)$$

with:

$N(E)$ is the net area of the photopeak with the energy E , unfolded with the spectrum software

t_r is the real time of measurement

C_θ is the dead time correction factor

C_{dec} is the decay correction factor

Then the spectral indexes, which describe the capture rate on ^{238}U per unit of fission, are given by:

$$\frac{C_8}{F} = Y \frac{A(E_c)}{A(E_f)} \frac{I_\gamma(E_f)}{I_\gamma(E_c)} \frac{R^P(E_f)}{R^P(E_c)} \frac{T(E_f)}{T(E_c)}. \quad (71)$$

The saturated count rates and the detection efficiencies are obtained from measurements. Some nuclear data is also required: fission yields, radioactive periods and gamma-ray emission probabilities. They can be extracted from the JEF2.2, JEFF3.1, or ENDF/B-VI.8 nuclear data libraries. Finally, relative reaction rate calculations must be performed to estimate average fission yields and efficiency transfer corrections. They will be described in the next section.

The overall uncertainty on this particular spectral index is simply obtained from the variance propagation relationship, given at the first order by:

$$\frac{u^2\left(\frac{C_8}{F}\right)}{\left(\frac{C_8}{F}\right)^2} = \frac{u^2(Y)}{Y^2} + \frac{u^2\left(\frac{A(E_c)}{A(E_f)}\right)}{\left(\frac{A(E_c)}{A(E_f)}\right)^2} + \frac{u^2\left(\frac{I_\gamma(E_f)}{I_\gamma(E_c)}\right)}{\left(\frac{I_\gamma(E_f)}{I_\gamma(E_c)}\right)^2} + \frac{u^2\left(\frac{R^P(E_f)}{R^P(E_c)}\right)}{\left(\frac{R^P(E_f)}{R^P(E_c)}\right)^2} + \frac{u^2\left(\frac{T(E_f)}{T(E_c)}\right)}{\left(\frac{T(E_f)}{T(E_c)}\right)^2}. \quad (72)$$

9.5 γ Heating Measurements

9.5.1 Principle

The gamma dose measurement is an important integral parameter in several situations where the heating due to energetic photons takes on some problems. This particularly applies for the heating in experimental devices inserted into irradiation cores. This dose can be measured using ionization chambers or using TLD. This thermo-luminescence is caused by irradiation beforehand by ionizing radiation. TL is only observed on non-metallic materials and mainly on crystallized ion composites. We consider a band gap insulating material, typically of a few eV. The impurities and effects caused by doping the material create the following electronic levels in the band gap:

- Confined levels (CL), generally close to the conduction band (CB) or the valence band (VB). They “capture,” trap electrons during irradiation and “free” them when sufficient thermal energy is provided.
- Recombination centers (RC), deeper in the gap, are where the electron/hole radiative exchange (emission of a visible photon) takes place when an electron is released from a confined level.

As these materials are insulators, an electron has a very short lifetime in the CB.

During irradiation by ionizing radiation (► Fig. 82), ionization of a certain number of atoms occurs; VB electrons are freed into the CB (1) in which they move freely whereas the holes created move into the VB. During this transitional phenomenon, two events may occur:

- The electron recombines with a hole (annihilation). If the recombination is radiative, the emission of fluorescence is observed. However, this band to band recombination is unlikely.

Figure 82
Irradiation

■ **Figure 83**

Thermal stimulation process

- The charges are trapped (2 and 2'). As the confined levels are metastable levels, the electrons can only be freed if they are provided with energy E required to make them pass into the CB from which the recombination step is possible.

Energy E can be supplied by a gradual increase of the crystal's temperature: this thermal excitation is called thermo-stimulation (➡ Fig. 83).

The electron will be unconfined (3) at a specific temperature of the defect with which the confinement is associated.

Once the electron is released, two events may occur:

- The electron is trapped again (4), however it will immediately "leave" as the temperature is too high
- It recombines with a hole (5). If the recombination is radiative, *emission of thermoluminescence* is observed, in the visible photonic and/or UV spectrum, the emission spectrum depends on the depth of the trap

If E is low (shallow trap for the temperature in question), the ambient thermal agitation is enough to provoke the release. The emission which can be observed is called phosphorescence. It takes place at ambient temperature.

9.5.2 γ Dose Calculation

Measurement of the gamma dose in mixed neutron – gamma field (n, γ), particularly in a hydrogenated environment, creates serious problems due to the sensitivity of most TLDs to neutrons with different energies. The signal emitted by the TLD can be interpreted as resulting from the sum of three terms, corresponding respectively to the following.

- The total gamma dose to be measured
- The parasite contribution of thermal and epithermal neutrons
- The fast neutron dose

In these conditions, the measured dose (D_{mes}) can be broken down according to the following relationship:

$$D_{mes} = hD_{tot} + k_{th}\Phi_{th} + h_{rap}D_{rap}, \quad (73)$$

where

h attributed to the total gamma dose depends on the spectral response of the TLD. It is given the same value if the spectrum of the photon component of the radiation field does not have energies which are too low (< 100 keV or too high > 10 MeV) with respect to the calibration radiation of cobalt-60. Prior knowledge of the predominant photon spectrum in the core is therefore necessary.

k_{th} [$\text{Gy}/(10^{12} \text{ n cm}^{-2})$], corresponding to the fluence of thermal neutrons Φ_{nth} , depends on the nature of the TLD and the neutron energy spectrum: it expresses the sensitivity of thermo-luminescent materials to thermal neutrons as the parasite response is mainly due to the latter.

h_{rap} [per neutron: Gy cm^{-2}] is minor in a fission field. This contribution is not currently taken into account, however some information can be found in literature.

Obtaining the γ dose of TLDs requires several preliminary TLD and calibration individual characterization steps. These steps then allow a gamma dose to be deduced from thermo-luminescent emissions, at the end of final irradiation in the reactor, after adjustment on the reactor's power.

9.5.3 The Different Types of TLDs Used

The different TL materials which are used are:

- $\text{CaF}_2:\text{Mn}$
- $\text{Fli}^7:\text{Mg,Ti}$ (TLD700 and MTS-7)
- $\text{Al}_2\text{O}_3:\text{C}$
- $\text{Al}_2\text{O}_3:\text{Na}$ (powder) (► [Fig. 84](#))

9.6 Neutron Noise Measurements

Measurement of the delayed neutron fraction falls under the category of so-called “neutron noise” measurements. Neutron fluctuation measurements are based on stable or transitional macroscopic statuses generated in low power reactors, for example, fissions or neutron sources, etc. Several methods exist and are applied in the critical mock-ups. They are classified into two categories:

- Pulsed methods: Feynman- α and Rossi- α
- Frequential methods: power spectral density (PSD), ^{252}Cf source

■ Figure 84

Example of TLDs used at EOLE, MINERVE and MASURCA

All these methods have been tested and their validation range estimated on MASURCA, as part of determination measurements for the reactivity of subcritical systems (MUSE program).

Here, the PSD method, implemented in EOLE, is of particular interest.

9.6.1 The Power Spectral Density (PSD) Method

This is a so-called “correlation” technique based on the study of correlations between detections at an instant t and $t + T$. It is based on the measurement of the reactor’s transfer function, given by the standard expression

$$|H(\omega)|^2 = \frac{\eta_0^2}{\left(\beta_{eff} - \rho - \sum_j \frac{\lambda_j^2 \beta_j}{\lambda_j^2 + \omega^2} \right)^2 + \omega^2 \left(1 + \sum_j \frac{\lambda_j^2 \beta_j}{\lambda_j^2 + \omega^2} \right)} \quad (74)$$

with the following approximations.

- Spatial effect not considered (point reactor approximation)
- Stable state: no reliance on time
- Low power, no counter-reaction effects

The most frequently used approximations are $\ell \gg \sum_j \lambda_j^2 \beta_j / \lambda_j^2 + \omega^2 \ll \beta_{\text{eff}} - \rho$ and the previous expression becomes:

$$|H(\omega)|^2 = \frac{\eta_0^2}{(\beta_{\text{eff}} - \rho)^2 + \omega^2 \ell^2}. \quad (75)$$

It involves a first rate filter for which the plateau is given by:

$$\omega \ll \frac{\beta_{\text{eff}} - \rho}{\ell} \quad \text{and} \quad |H(\omega)|_{\text{plateau}}^2 = \frac{\eta_0^2}{(\beta_{\text{eff}} - \rho)^2} \quad (76)$$

and the cut-off frequency is expressed as,

$$\omega_c = \frac{\beta_{\text{eff}} - \rho}{\ell} \quad \text{or} \quad f_c = \frac{\beta_{\text{eff}} - \rho}{2\pi\ell}. \quad (77)$$

The statistical nature of the reactor noise helps determine the average level of the neutron population. It can be shown that the spectral density of the equivalent noise source is given by

$$\langle |S|^2 \rangle = 2 \left(\frac{\eta_0}{\ell} \right)^2 \frac{D}{F}, \quad (78)$$

where

$$D = \frac{\overline{v(v-1)}}{\bar{v}^2} \text{ is the Diven factor,} \quad (79a)$$

$$F = \frac{1}{v} \frac{\eta_0}{\ell} \text{ } F \text{ is the total number of fissions in the core per time unit.} \quad (79b)$$

It represents the distribution of power on the frequency axis.

9.6.2 Experimental Principle

Measurement of the transfer function and the PSD is carried out using specific fission chambers, highly loaded, operating in standard mode and placed around the core, as close as possible to the fuel. They are positioned symmetrically in order to increase the probability of detecting correlated events. The signal coming from these chambers is then filtered of its continuous component, seen as white noise. It is shown that the final expression allowing the PSD to be linked with the delayed neutron ratio is given by:

$$\frac{DSPI}{V_1 V_2} = \frac{2D}{F} \times \frac{1}{(\beta_{\text{eff}} - \rho)^2}, \quad (80)$$

where V_1 and V_2 are the voltages of fission chambers placed in the core.

The fraction of delayed neutrons is obtained from this relationship

$$\beta_{\text{eff}}^2 = \frac{2D}{F(1 + \rho)^2} \times \frac{V_1 V_2}{DSPI}. \quad (81)$$

The Diven factor is calculated. It depends relatively little on the case in question and its value is often close to $0.800 \pm 2\%$ (1σ). The other sizes are determined experimentally.

The fission integral measurement, in particular, is obtained using $F = P/F_N$ where P is the core's power (Watt)

$F_N = 3.2 \times 10^{-11}$ W/fission s is the average energy released by fission.

The power is measured using a calibrated fission chamber, placed at the center of the core. The power is then expressed as:

$$P = f \times \frac{C}{m_5} \quad (82)$$

with

$$f = M_5 \times \frac{\sigma_{f5}^{core}}{\sigma_{f5}^{chamber}} \times \frac{1}{\alpha\beta} \times \frac{I_{fT}}{I_{f5}} \times F_N, \quad (83)$$

where C is the count rate of the chamber, m_5 is the ^{235}U mass in the chamber, M_5 is the ^{235}U mass in the core, σ_{f5} is the fission cross-section of the ^{235}U , α is the axial shape factor, β is the radial shape factor, and I_f is the fission integral (core or chamber).

The total uncertainty on the value of the delayed neutron fraction is approximately 1.6%, without taking into account the uncertainty stemming from the Diven factor which contributes 3% at 1σ on the β_{eff}^2 .

10 Conclusion

This chapter indicates the key-role of the Zero Power Reactors for the development of a sustainable nuclear energy.

It has shown that whatever the progress of simulation tools, a complementary experimental program for qualification and validation is often necessary.

During these last decades, the ZPR help the various entities working in the nuclear energy domain (utilities, technical support to regulatory bodies, research Institutes, etc.) to improve their knowledge on reactor physic and nuclear data (reduction of target uncertainties, better estimation of fundamental parameter such as k_{eff} , beta effectif, power map, etc.).

As a positive feedback, we can quote the improvement of Nuclear Power Plant competitiveness (Higher Burn-up, new fuel design, new core design, etc.), life time extension (fluence dosimetry on reactor vessel and internals, etc.) safety (neutron absorber, reactivity coefficient, etc.) and the proposal of new data libraries based on fundamental nuclear data.

Moreover, these ZPR are also important for the design of new generation of MTR for qualification of new fuel and associated calculation tools.

Last but not least, these ZPR have been and will stay of particular importance for training of young scientists and Engineers and operating teams working in the field of nuclear reactors (research reactors or power reactors).

Abstract: This chapter describes Korean experiences and accomplishments in construction, operation, and design development of nuclear power plants. Recognizing domestic energy-resource scarcity, Korea has steadily constructed, operated, and improved nuclear power plants based on self-reliant technologies and accumulated experiences. This chapter describes specifically i) two pressurized light water reactor models (OPR1000 and APR1400) currently being built and to be built in the future, and ii) experience with the pressurized heavy water reactors (CANDUs) built and in operation, in the Republic of Korea.

1 New Pressurized LWRs Built (or To Be Built) in the Republic of Korea

1.1 Introduction

Since 1978, when Kori Unit 1 nuclear power plant had commenced commercial operation, Korea has successfully constructed and operated nuclear reactors. As of 2006, 20 nuclear power plants are in operation, which cover about 40% of total electricity generation in Korea. As a subsidiary of Korea Electric Power Corporation (KEPCO), Korea Hydro and Nuclear Power (KHNP) as the nuclear power utility of Korea has operated several types of qualified nuclear reactors, which include Westinghouse- and CE-designed PWRs, Framatome-designed PWRs, and Canadian PHWR CANDU reactors. In spite of various operating reactors, KHNP showed outstanding operation capability. The average annual capacity factor in 2005 for the 20 operating nuclear units was 95.5% and they have achieved over 90% continuous annual average capacity factor since 2000.

➤ *Figure 1* shows a history of nuclear power plant introduction in Korea. The 1970s was a period of introduction of the first nuclear power plant in Korea. This period started with the construction of Kori Unit 1 nuclear power plant (Westinghouse PWR) with a turnkey contract. One unit was built during this period. The 1980s was a period of induction of domestic companies to participate in the construction with an individualized separate contract for each company. During this period, seven PWR units had been constructed with partially acquired foreign nuclear technology. Through the Nuclear Power Plant Standardization Program, which began in 1984 and continued for over 10 years, KHNP developed Optimized Power Reactor 1000 (OPR1000), as a Korean standard model, based on operational experiences as well as construction and maintenance experiences. In particular, the Yonggwang #3&4 (Combustion Engineering PWR) project provided valuable experience in OPR1000 development. The OPR1000 design aimed at maximizing operational efficiency and minimizing inadvertent effects on operators and environment.

In continuation, the 1990s was a period of technological self-reliance. Self-reliance in terms of nuclear technology was the main theme of this period by designing the OPR1000 without relying on foreign companies. Six units began construction during this period, and it was completed by 2005 (Ulchin Unit 3 is the first OPR1000 nuclear power plant that has been in commercial operation since 1998). Four additional OPR1000 units are currently under construction.

The 2000s is a period of development of an advanced nuclear reactor. The repeated constructions and the operation experiences of OPR1000 brought forth internationally competitive construction technology and outstanding operation and maintenance capabilities. By adopting advanced design features based on the self-reliant technologies, Korea developed the Advanced

■ Figure 1

History of Korean nuclear technology development (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

Power Reactor 1400 (APR1400) next to meet Korean Utility Requirement Document (KURD) that reflects the ALWR design requirements developed by Electric Power Research Institute (EPRI), European Utilities Organization, and others. The APR1400 design evolved from the accumulated experience of nuclear power plant construction and development for 3 decades in Korea.

Korea is a unique country that has steadily constructed and updated nuclear power plants since the 1980s. Based on self-reliant technologies and experiences from the design, construction, operation, and maintenance of OPR1000, the APR1400 has been developed by adopting advanced design features to enhance plant safety and economical efficiency. The APR1400 is an embedment of all these experiences and technologies for the past 30 years in Korea.

The APR1400 obtained its design certification (DC) from Korean nuclear regulatory body in May 2002. The construction of Shinkori #3&4 commenced as the first APR1400 plants in 2007, and they are planned to start commercial operation in 2013 and 2014, respectively. Two units of Shin-Ulchin #1&2 are planned as the second construction project of the APR1400.

The first CANDU began operation in 1983, and three additional units in 1997, 1998, and 1999.

1.2 OPR1000 (Optimized Power Reactor 1000)

OPR1000 is a PWR model, developed as a result of the plant standardization program and incorporating construction and operating experience in Korea. Six units are currently in operation and four units are under construction (expected to be completed during 2009–2011) (☛ Fig. 2).

OPR1000 Development process

Figure 2
OPR1000 development process (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

Figure 3
Building arrangement improvement (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

1.2.1 Design Description

Building and Structure

The general arrangement of OPR1000 is based on the twin-unit concept with a slide-along arrangement of one Compound Building for two units, which comprise common facilities such as the Secondary Auxiliary Building, Access Control Building, and Radwaste Building (Fig. 3 and Table 1). The merits of improved design are:

1. Elimination of Radwaste Tunnel
2. Minimization of the length of underground common tunnel
3. Reduction of building volume and occupational radiation exposures

■ **Table 1**

Reactor containment building design values

Parameter	Design value
Leak rate (%/day)	0.2 (for 24 h), 0.1 (after 24 h)
Design pressure (psig)	57
Free volume (ft ³)	2.727×10^6
Height (ft)	216
Diameter (ft)	144

Sources: Data compiled from Ulchin Unit 5, 6 Final Safety Analysis Report and Shinkori Unit 3, 4 Preliminary Safety Report.

Primary System

Reactor Coolant System The reactor coolant system (RCS) consists of two heat-transfer loops forming a barrier to release radioactive materials from reactor core to secondary system and containment atmosphere. The main components are a reactor vessel, two steam generators, and four reactor coolant pumps that are symmetrically located on opposite sides of the reactor vessel with a pressurizer on one side; all these components are located in the Containment Building and connected through pipe assemblies. The pressure-retaining components for the reactor coolant pressure boundary are fabricated in accordance with the ASME Boiler and Pressure Vessel Code, Section III.

Reactor Core The reactor core consists of 177 fuel assemblies, which include 73 control element assemblies (CEAs) and 45 in-core instrument (ICI) assemblies.

The core is now fueled with PLUS7 advanced fuel assemblies with maximum discharge rod burnup of 60,000 MWD/MTU (➤ [Table 2](#)) (PLUS7 Fuel Design 2006). The refueling cycle length is 18 months with gadolinia burnable absorber. PLUS7 is a new fuel design, replacing GUARDIAN (Fuel Design Report 1995). More detailed description for PLUS7 is provided in ➤ [Sect. 1.3.1](#).

Reactor Vessel The reactor vessel (RV) is fabricated by ring-forged shells. These ring-forged shells eliminate the need for longitudinal seam welds, thereby reducing the production and inspection time. The material for reactor vessel head penetration nozzles is Alloy 690 to get better resistance against many corrosive aqueous media at high-temperature environment. To adopt R/C inspection camera robot for the periodical inspection of reactor vessel head penetration area, reactor vessel head insulation has been designed to have clearance between reactor vessel head and insulation and changed from fixed type to removal type. The weld preparations for head penetration nozzles are optimized to get better welding and minimum weld-deposited metal (➤ [Fig. 4](#) and ➤ [Table 3](#)).

Reactor Vessel Internals The OPR1000 reactor vessel internals (RVI) design contains very limited number of bolts to eliminate the possibility of loose parts during operations. Upper guide structure (UGS) lower flange and support plate have been designed as integral type, which increases the structural integrity of RVI and minimizes the possibility of deformation from related weld work. Concerning the flow-induced vibration, the integrity of RVI had been verified through the comprehensive vibration assessment program (➤ [Fig. 5](#)).

Steam Generator OPR1000 has two steam generators. Each steam generator includes U-tube bundle, evaporator with integral economizer, double main feed lines and single auxiliary feed line, double steam lines with integral flow restrictors, high-capacity moisture separators, and high-efficiency dryers. It is designed to have an 8% tube plugging margin to ensure a longer full power life. A major improved feature incorporated into the steam generator design is the use of thermally treated corrosion-resistant material in U-tubes, namely Inconel-690 instead of previous Inconel-600. To support the tubes, vertical and horizontal strips are added at the inner and upper side of the tube bundle and reducing the tube wear caused by flow induced and low frequency vibrations. Feedwater is shared between the economizer and downcomer region of the steam generator for improving feedwater recirculation. This results in a reduction of water hammer in the feedwater system, and increases the thermal efficiency (► [Table 4](#)).

■ **Figure 5**
Reactor vessel (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

Pressurizer The pressurizer design adopts the EPRI's requirements for advanced light water reactor (ALWR). The pressurizer volume is about 30% larger than the volume of System 80 Plants. This improves plant response capability at transient and accident conditions.

Sufficient RCS depressurization and overpressure protection capabilities are provided by reactor coolant gas vent system, safety depressurization system and three pressurizer safety valves installed at the top of the pressurizer. Replaceable 36 heaters with total 1,800 kW capacity at the bottom head control the system from under-pressurization. To resist

high-temperature/pressure transient during operation, Inconel-690 is used for heater support and spray head support in accordance with the ASME section NB requirement (● [Table 5](#)).

Control Element Drive Mechanism The control element drive mechanism (CEDM) is an electromechanical device that provides controlled linear motion to CEA through an extension shaft assembly (ESA) in response to operating signals received from CEDM control system. CEA motion occurs when power is sequentially applied to the series of electrical coils located outside of the primary water pressure housing. In an emergency shutdown, the CEAs are inserted into the core by gravity upon initiation of a scram signal. As an advanced design feature, the seismic support system has been incorporated into the CEDM to transmit seismic load from CEDMs and integrated head assembly (IHA) to refueling pool wall through the seismic restraint. The seismic caps are installed to each CEDM top-side and connected to seismic ring beam, which

■ Table 6

Sources: Data compiled from Ulchin Unit 5, 6 Final safety analysis report and Shinkori Unit 3, 4 Preliminary Safety Report.

is connected to seismic restraint. The addition of these seismic support systems contributes to reduction of the seismic loads from the CEDM cable. Also, CEDMs are operable for cumulative 100,000 ft travel length as minimum, move 30 in./min at normal operating condition, and are lubricated by primary coolant (➤ Table 6).

Containment Spray System The containment spray (CS) system as an engineered safety feature (ESF) reduces containment pressure and temperature following a postulated loss of coolant accident (LOCA) or main steam-line break (MSLB) inside containment. It also removes radioactive fission products from the containment atmosphere, and mixes containment atmosphere to prevent local accumulation of combustible gases following a postulated LOCA.

The CS heat exchanger of OPR1000 was eliminated by sharing the shutdown cooling heat exchanger for cooling sprayed water. This technical improvement results in significant cost reduction.

Secondary System

Main Steam System The main steam system is designed to maintain functionality during and following a safe shutdown earthquake (SSE). The main steam system contains safety valves to prevent system pressure from exceeding preset limits imposed by code requirements. Also, the main steam system contains main steam atmospheric dump valve on each of the four main steam lines to allow controlled cooldown capability for steam generator when main steam isolation valves (MSIVs) are closed.

The main steam system can deliver steam to the turbine bypass system to discharge steam to the condenser and to the atmosphere to permit load rejection of any magnitude including turbine trip from full power without reactor trip or opening pressurizer safety valve and/or main steam safety valve. The turbine bypass system can provide controlled plant cooldown capability after reactor trip by diverting steam directly to the condenser and/or to the atmosphere (➤ Table 7).

Main Feedwater System The feedwater system consists of three 55% capacity variable speed turbine-driven pumps, three 55% capacity motor-driven booster pumps, and three stages of feedwater heaters. Six closed-type high-pressure feedwater heaters consist of two 75% capacity parallel trains as three heaters in each train. Three turbine-driven pumps and three motor-driven booster pumps are operated in normal plant operation. When one of the three operating feedwater pump trips, the remaining two pumps can supply enough feedwater to

steam generators at the maximum of 110% rated flow against steam generator pressure without reactor trip. The low-low net positive suction head (NPSH) trip interlocks for feedwater pumps/feedwater booster pumps are provided for the low-low NPSH protection of the feedwater pumps/feedwater booster pumps. Appropriate time delays and two out of three logic for the NPSH trip signal are provided to avoid immediate trips. The feedwater system includes one 5% capacity motor-driven start-up feedwater pump to be used during start-up, shutdown, and hot standby operation. This standby feedwater pump can prevent reactor scrams caused by feedwater shortage (➤ [Table 8](#)).

Turbine The turbine of OPR100 is thermodynamically designed to obtaining high efficiency and economical steam-path arrangement. OPR100 has one double-flow high-pressure turbine and three double-flow low-pressure turbines. The turbine of OPR1000 is six-flow tandem-compound type with rated speed 1,800 rpm. Especially, mono-block rotor design is applied to remove stress corrosion cracking at shrunk-on region, crack initiation at contact surface of disk and shaft, and poor dynamic stability. With the fast developed forging technology, the turbine manufacturer applied mono-block-type rotor to OPR1000, and it could fully make up for the disadvantage of existing shrunk-on type rotor. Also, mono-block completed rotor package from the manufacturing shop makes large reduction of site construction period (➤ [Table 9](#)).

Generator The generator system of OPR1000 consists of the generator itself and auxiliary systems such as stator cooling water system, gas control system, and hydrogen seal oil system. Stator of the generator takes highly reliable F-class Micapal II insulation system and brazing technology. Rotor also takes highly reliable F-class insulation system and radial flow cooling method (➤ [Table 10](#)).

Moisture Separator Reheater (MSR) The moisture of wet steam expanded at high-pressure turbine (HP TBN) is separated and reheated through moisture separator reheater (MSR) to protect the corrosion of the LP TBN blades. Therefore, the enhanced performance of MSR increases the cycle efficiency and the lifetime of the turbine.

Application of Plate-Type Heat Exchanger The plate-type heat exchangers are adopted in the component cooling water system and the spent fuel pool cooling and cleanup system instead of shell-tube-type heat exchanger. The plate-type heat exchangers have greater heat-transfer efficiency than shell-tube-type heat exchangers. Small size and low weight reduce initial installation cost, while high heat-transfer efficiency makes low operating costs. With larger free space, easy maintenance is available. The number and specifications of the plates can simply be increased, reduced, or altered as required.

Enhanced Intake and Discharge System Intake channel design for the circulating water system is enhanced by reducing the number of traveling screens and pumps. It improves the operability of pumps and traveling screens. OPR1000 apply submerged intake and discharge system with multi-velocity cap and diffuser. It reduces temperature rise of seawater from discharged cooling water and minimizes the effect on environment and recirculation rate of thermal discharge.

Control and Electrical Systems

Station Power System The switchyard is a 345 kV full gas insulated substation with a breaker-and-a-half configuration. The Station Power System consists of the main power (MP), auxiliary

power (AP), DC & IP, emergency diesel generator, and alternative alternate current diesel generator (AAC DG). The normal power source for class 1E and nonclass 1E loads is the off-site power source and the generator. If the normal power source is not available, class 1E and nonclass 1E loads are covered by the standby off-site power source via the standby auxiliary transformers as an alternative source.

Electric power necessary for the class 1E systems is supplied through four alternative ways as follows:

1. Normal off-site power and the in-house generation (PPS-1)
2. Off-site power connected through the standby auxiliary transformers (PPS-2)
3. Two class 1E emergency diesel generators (EDG)
4. Alternate AC diesel generator (AAC DG)

The on-site emergency power supply is ensured by two independent-class 1E diesel generators connected to each 4.16 kV class 1E bus. The alternate AC source adds more redundancy to the electric power supply, although it is not a safety-grade system. The nonclass 1E alternate AC is to cope with station blackout (SBO) condition where there is a high potential of transients progressing to severe accidents.

Plant Control System (PCS) The balance of plant (BOP) plant control system (PCS) remotely controls and monitors most of the safety-related and non-safety-related plant equipment including engineered safety feature actuation system (ESFAS) from the main control board or remote shutdown panel. PCS is divided into safety-related and non-safety-related subsystems. Each subsystem consists of control cabinets that have on-off control and analog control function, communication devices, human-machine interface (HMI), and other auxiliary devices. In addition, the PCS interfaces with the T/G control system and radiation monitoring system to provide the operating status of various equipment and trend information of diverse process variables to operators and the plant monitoring and annunciator system (PMAS).

PCS for OPR1000 uses the distributed control system (DCS) that incorporates the state-of-the-art digital technology. It uses the multi-loop control concept where one controller executes the control logic for several equipments. In order to improve the reliability and safety of the system, the power, communication devices, and controllers are designed by redundant concept. Also, the control system for radwaste system is designed as screen-based control instead of using conventional control board to improve the operational convenience. In order to secure the safety of the system, PCS-adopted stringent design criteria such as environmental requirement for seismic and electromagnetic interference/radio frequency interference (EMI/RFI).

Main Control Room (MCR) To enhance the operational convenience and reliability, human factors engineering (HFE) technology is adopted systematically (🔍 Fig. 6). The design of OPR1000 embodies human-centered man-machine interface (MMI) technology that meets latest licensing requirements, by developing and applying systematic HFE program that incorporates:

1. Review of operating experience
2. Functional requirement analysis (FRA) and functional allocation (FA)
3. Task analysis (TA)
4. HFE verification and validation (V&V)

■ Figure 6

Main control room (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

1.2.2 Major Safety Design Features

Safety

Safety Enhancement Probability safety assessment (PSA) has been employed during the design of each OPR1000 power plant. As a measure of the plant safety, core damage frequency (CDF) for internal initiating events during at-power operation was used. Based on the PSA results of the original design, several design changes to improve the plant safety were adopted:

1. Add safety depressurization system (SDS) for feed and bleed operation for total loss of feedwater event.
2. Add alternative AC power source for station blackout.
3. Change the design of auxiliary feedwater system to improve reliability.

Defense in Depth The safety concept of OPR1000 is based on the principle of defense-in-depth concept by providing the following multiple, diverse principles for accident prevention and mitigation of the consequences:

1. High-quality process systems to accommodate plant transient and to minimize the likelihood of the accident.
2. Reliable safety systems for reactor shutdown, emergency core cooling, decay heat removal, and containment heat removal.
3. Reliable safety support systems to provide services to the safety systems and other mitigating systems.
4. Passive heat sink to increase resistance against both design basis events and severe accidents.
5. Application of multiple barrier concept consisting of
 - a. Fuel pellet and cladding
 - b. Reactor coolant pressure boundary
 - c. Steel-lined prestressed concrete containment
 - d. Exclusion area

The design of the safety systems follows the principles of separation, diversity, and reliability. High degrees of redundancy concept are adopted in the system design to ensure that the safety functions can be carried out, even when systems or components are impaired. Protections against seismic, flooding, and fire events are also provided to ensure highly reliable and effective mitigation of postulated events, including shutdown and severe accidents.

ALARA Concept As low as reasonably achievable (ALARA) philosophy is applied from the initial design of OPR1000 and implemented and documented via internal design reviews. These reviews are conducted and documented in conformance to the Korean Atomic Energy Act (KAEA). It also satisfies the ICRP60 recommendation. The plant design is reviewed, updated, and modified continuously during the design and construction phases. This includes plant layout, shielding, ventilation, and monitoring system design with traffic control, security, access control, maintenance, in-service inspection, and radiation protection aspects to ensure that the overall design results of radiation exposure will achieve the ALARA philosophy. ALARA design improvements of OPR1000 include the use of low cobalt materials for steam generator tubes and valve hard facing material and adoption of an extended fuel cycle length that reduces the frequency of extensive maintenance work. These improvements are expected to result in an annual occupational radiation dose (man-Sv) that would be less than the dose for conventional PWRs. Since Yonggwang (YGN) 3&4, OPR1000's annual occupational radiation dose was gradually reduced. The annual occupational dose for latest OPR1000 is expected to be about 1.07 man-Sv per unit (Ulchin Unit 5, 6 FSAR 2003).

Severe Accident

The design principle of OPR1000 is to prevent and mitigate severe accident events and minimize their consequences. The systems and features of OPR1000 for this purpose ensure the public safety by maintaining the integrity of the containment and limiting the release of radioactive materials within the allowable limits (Ulchin Unit 5, 6 FSAR 2003).

Reactor Cavity Design The reactor cavity structure of the OPR1000 is designed to suppress the release of corium debris into the containment atmosphere to preclude high-pressure melt ejection (HPME) and direct containment heating (DCH) and to prohibit melt-through of the reactor cavity floor concrete.

Corium Debris Collection Chamber When the reactor vessel breaches under high pressure conditions, the molten corium ejected into the reactor cavity is released into the containment atmosphere through the ICI cavity – ICI guide tube passway. The collection chamber is designed to confine and to suppress the release of corium debris to the containment atmosphere.

Flow Restrictor A flow restrictor is used to block the release of corium debris to ICI guide tube exit. The flow restrictor can mitigate the DCH phenomenon by restricting the flow of high-pressure corium as much as possible.

Reactor Cavity Floor Radioactive materials can be released due to melt-through of the reactor cavity floor during molten core–concrete interaction (MCCI). To prevent melt-through of the concrete floor, the cavity floor thickness is modified.

Mitigation System Reactor Cavity Flooding System (RCFS)

During a postulated severe accident, MCCI may threaten the integrity of the containment. To prevent MCCI, reactor cavity flooding system (RCFS) is installed in OPR1000, which injects cooling water into the reactor cavity. For this purpose, flanged branch connection is provided to supply cooling water into the reactor cavity from the fire protection system.

Hydrogen Control OPR1000 adopted passive autocatalytic recombiners (PARs) instead of conventional active thermal hydrogen recombiner for the hydrogen control in the reactor containment to improve the safety following DBA LOCA. Although the PAR system is basically intended for design basis hydrogen control for OPR1000, it is also expected to function during severe accidents as the passive characteristics for hydrogen removal. The capacity and the number of PARs are determined to limit the hydrogen concentration below the flammable limit following a DBA LOCA.

Characteristics of PARs are:

1. Hydrogen control during all design basis accidents
2. Total prevention of combustion and exclusion of combustion loads during DBA
3. Simple passive design without moving parts
4. No external power supply
5. Self-starting and self-feeding operation
6. Easy installation and in-service inspection

Besides, OPR1000 adopted hydrogen ignition system (HIS) to maintain the hydrogen concentration within design limit. The HIS consists of 20 thermal plug-type hydrogen igniters located throughout containment and is capable of igniting the hydrogen to facilitate controlled burning. The hydrogen igniters are powered by electrically isolated Class 1E power bus.

Containment Filtered Vent System (CFVS) During a postulated severe accident, generation of large amount of steam or noncondensable gas can cause over-pressurization of the containment. To prevent the over-pressurization, containment penetration of OPR1000 is exclusively assigned in conjunction with the containment-filtered vent system (CFVS). And for future use, a dedicated 3 ft diameter containment penetration and the space are provided.

1.3 APR1400 (Advanced Power Reactor 1400)

APR1400 stands for advanced power reactor, which is a 1,400 MW pressurized water reactor developed in Korea. Based on the self-reliance technologies and experiences from the design, construction, operation, and maintenance of OPR1000, APR1400 adopts advanced design features to further enhance plant safety, economical efficiency, and convenience of operation and maintenance (➤ Fig. 7).

1.3.1 Design Description

Building and Structure

The general arrangement of APR1400 has been developed based on the twin-unit and slide-along concepts. The layout of APR1400 can be divided into Nuclear Island (NI) and Turbine

Figure 7

Flow diagram of APR1400 development (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

Island (TI). The NI consists of Reactor Containment Building (RCB), Auxiliary Building (AB), and Compound Building (CB). The CB includes access control area, radwaste treatment area, and hot machine shop as common facilities for both units. The TI is composed of Turbine Building (TB) and Switchgear Building (SB). The RCB is located at the center of the NI and is placed on a common basemat with the AB, which houses EDGs and fuel handling area (FHA). The layout of NI improves the structural safety margin against external events such as a seismic event. The layout of AB, particularly for the physically separated arrangement of safety equipment, is designed to enhance plant safety. As examples, four-train safety injection systems (SISs) and two set of EDGs are arranged in such a way that each one is placed in the physically separated division of AB. This configuration prevents propagation of system damage by internal and external events such as flood, fire, security threat, and sabotage. Other internal structures are also arranged to improve maintainability, accessibility, and convenience of equipment replacement (► Fig. 8).

Reactor Containment Building The RCB is a prestressed concrete structure in the shape of a cylinder with a hemispherical dome as seismic category I and is founded on a common basemat with the AB. The inner surface of RCB is steel-lined for leak-tightness and a protective layer of concrete covers the portion of the liner over the foundation slab. The in-containment refueling water storage tank (IRWST) is located in the RCB, in an annular-shaped configuration between the secondary shield wall and the containment wall. Therefore, the safety injection pumps (SIPs) always take water from the IRWST without switching its suction from the IRWST to the containment sump for the long-term cooling following a LOCA. As measures to mitigate the consequences of severe accidents, the reactor vessel cavity is designed for heat-transfer area

Figure 8

Quadrant arrangement of auxiliary building (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

Figure 9

IRWST structure (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

of corium to be not less than $0.02 \text{ m}^2/\text{MW}$, such that it is cooled and solidified on the cavity floor. Also, the convoluted vent path of the reactor vessel cavity prevents the molten-core debris from being released into the containment atmosphere. In order to improve the convenience of maintenance, the equipment hatch, the arrangement of the structures, and the polar bridge crane are designed for a steam generator to be replaced in one piece. Also, work platforms are installed to enhance the convenience of in-service inspection (ISI) for steam generators and maintenance of reactor coolant pumps (RCPs) (► Fig. 9 and ► Table 11).

■ Table 11

Diameter (ft)	150

Source: Data compiled from Shinkori Unit 3, 4 Preliminary Safety Report.

■ Figure 10

Common basemat of containment building and auxiliary building (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

Auxiliary Building The AB is designed with reinforced concrete structure as seismic category I and placed on a common basemat with the RCB. It wraps around the RCB with a quadrant arrangement. The AB houses the MCR, EDGs room, FHA, and the safety-related components such as SIS. The systems and internal structures in the AB are arranged to provide physical separation for minimizing the hazard from internal and external events such as flood, fire, security problem, and sabotage without adversely affecting accessibility. The safety equipment is spatially separated to enhance its actuation reliability. Each train of SIS, which consists of four trains, is located in each separate division. The EDGs are also spatially separated on opposite sides. In order to improve the convenience of operation and maintenance, the internal layout of the AB is designed to provide sufficient space and lifting rig for replacing heat exchangers and replace a generator of EDG without removing the outer wall. The technical support center (TSC) is located adjacent to the MCR to improve communication between operators and technical crews during abnormal plant situations. The passages are designed for visitors and plant crews not to interfere with each other in the FHA, the MCR, and turbine-operating floor. And the internal arrangement of components is divided into the radiation area and clean area to reduce the occupational exposure dose (➡ Fig. 10).

Compound Building As a common facility for both units, the Compound Building (CB) is designed with reinforced concrete structure as seismic category II. This building houses an access control area, a radwaste treatment area, primary and secondary sampling laboratories, and a hot machine shop. This arrangement makes access from each unit more convenient and reduces the size of the power block by making it more compact.

Turbine Building The TI consists of the TB and SB arranged in the radial direction to the NI. Both buildings are situated on a common basemat and designed with steel structure and reinforced concrete turbine pedestal as seismic category II. The TB encloses the components that constitute heat cycle and produce electricity. The SB houses the electrical distribution equipment. The conventional construction method for outdoor underground facilities delays the construction because of repeated digging and filling for the installation of various underground equipments. To reduce the construction schedule, the underground common tunnel is designed to accommodate all underground facilities in the base floor of the TB. In addition, for the effective maintenance, the whole demineralizers in the plant are located at the same level.

Primary System

Reactor Coolant System The core outlet temperature is lowered to increase the core thermal margin. This contributes to the decreased unplanned reactor trips during normal operation and the enhancement of the operational flexibility. In addition, the reduction of the core outlet temperature relieves the degradation of the steam generator tube due to the stress corrosion by adopting Inconel-690 as the steam generator tube material, which is known to be more resistant to the stress corrosion cracking than Inconel-600 of the conventional plants. The pressurizer volume is designed to be larger than those of the conventional plants. This design makes the APRI400 accommodate transients without power-operated relief valves (PORVs) and minimizes unplanned reactor trips during the transients. The pilot-operated safety relief valves (POS RVs) are used to perform the functions of pressurizer safety valves (PSVs) and safety depressurization valves (SDVs). This change ensures reliable valve operation without chattering and leakage for any type of discharge flow condition and allows remote manual operation of valves under postaccident conditions. The POS RVs perform the function of pressure relief for RCS overpressure transients and RCS depressurization for the feed and bleed operation. Moreover, during severe accidents (SAs), these valves relieve the RCS pressure rapidly to prevent the high-pressure ejection of molten core that may induce direct containment heating (► Fig. 11).

To reduce unplanned reactor trips, the core thermal margin is increased by more than 10% (compared to OPR1000) by lowering the core outlet temperature and increasing the RCS coolant flow. In addition, the pressurizer volume relative to power is enlarged to enhance the capability of coping with the transients (► Table 12).

Reactor Vessel and Internals The reactor vessel consists of a vertically mounted cylindrical vessel welded with a hemispherical lower head and a removable hemispherical upper closure head (► Fig. 12 and ► Table 13). The internal surfaces that are in contact with the RCS coolant are clad with austenitic stainless steel to prevent corrosion. The reactor vessel is manufactured with three shell sections, a vessel flange, and a hemispherical bottom head. The three shell sections, bottom head forging, and vessel flange forging are welded together, along with four inlet nozzle forgings, two outlet nozzle forgings, four direct vessel injection (DVI) nozzle forgings, and 61 ICI nozzles. The upper closure head is fabricated separately and is bolted to the reactor vessel. The dome and flange are welded together to form the upper closure head, on which the CEDM

■ Figure 11

Reactor coolant system (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

nozzles are welded. The nil ductility reference temperature (RTNDT) of the reactor vessel is lowered from 10°F of the conventional reactor vessel to -10°F by using low carbon steel, which has lower contents of Cu, Ni, P, and S than those of the conventional reactor. This material improvement extends the lifetime of the reactor vessel to 60 years. In addition, the Cobalt (Co) content in the reactor vessel material is lowered to reduce the occupational exposure dose. The reactor vessel internals of the conventional plant are fabricated into three parts of upper guide structure, core support barrel, and lower support structure. This compares with the reactor vessel internals of the APRI400, which are manufactured into two parts by integrating the core support barrel and lower support structure. This improvement contributes to the shortening of the construction schedule (Shinkori Unit 3, 4 PSAR 2008).

Reactor Core The reactor core consists of 241 fuel assemblies, which include 93 CEAs and 61 ICI assemblies. The core is designed for the refueling cycle to be greater than 18 months, with maximum discharge rod burnup of 60,000 MWD/MTU, and the thermal margin to be increased by more than 10%. This core design leads to the improvement of the economical efficiency and safety by increasing the plant availability factor with a longer refueling cycle and the reduction of unplanned reactor trips.

APRI400 uses the advanced fuel assembly, named PLUS7 (► Fig. 13) (PLUS7 Fuel Design 2006). PLUS7 is a new fuel design, enhanced in thermal hydraulic and nuclear performance and structural integrity compared with conventional fuel assemblies. The mixing vanes with high thermal performance, which induce a relatively small pressure loss, are adopted in all mid-grids to increase the thermal margin by more than 10% (than GUARDIAN). This

has been confirmed in critical heat flux (CHF) test. The batch average burnup is increased to 55,000 MWD/MTU by optimizing the fuel assembly and fuel rod dimensions and adopting an advanced Zirlo alloy as fuel clad. The neutron economy is improved with the introduction of the axial blankets at both ends of the pellet region and the optimization of the fuel rod diameter. The mid-grid buckling strength has been increased using straight grid straps and optimizing grid height. These design improvements increase the seismic resistance for the fuel assembly to maintain its integrity even under severe seismic-related accidents. The conformal type contact geometry between the mid-grid spring and fuel rod increases the in-between contact area to improve the resistance capacity for fretting wear. The debris-filter bottom nozzle (DFBN) is adopted to trap most debris before they enter the fuel assembly. This increases the debris-filtering efficiency and reduces fretting wear-induced fuel failures (► [Tables 14](#) and ► [15](#)) (Ulchin Unit 3, 4 RTSR 2005).

Control Element Assembly The CEA is composed of 12 fingers full strength, 4 fingers full strength, and 4 fingers part strength CEAs (► [Table 16](#)). Neutron-absorbing material is contained within a cylindrical sealed metal tube. The absorber material used for full strength control rod is boron carbide (B₄C) pellets. Inconel-625 is used as the absorber material for the part-strength control rods.

Figure 12
Reactor vessel (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

Integrated Head Assembly The reactor vessel upper closure head area of the conventional plant consists of CEDM cooling system, cooling shroud assembly, heat junction thermocouples, missile-shielding structure, and head lift rig (► [Fig. 14](#)). These components are usually disassembled, separately stored, and reassembled during every refueling outage. The IHA is applied to simplify the structure configuration on the reactor vessel upper closure head region and to improve the convenience of maintenance. All components on the head region are handled as single unit to reduce the occupational exposure dose of the maintenance personnel, the space required for equipment storage, and to shorten the overhaul duration (Shinkori Unit 3, 4 PSAR 2008).

Pressurizer The pressurizer is a vertically mounted cylindrical pressure vessel. Replaceable direct immersion electric heaters are vertically mounted in the bottom head (► [Table 17](#)). The pressurizer is furnished with nozzles for the spray, surge, POSRVs, and pressure and level instrumentation. A manway is provided in the top head for access for inspection of the pressurizer internals. The pressurizer surge line is connected to one of the reactor coolant hot legs and the spray lines are connected to two of the cold legs at the reactor coolant pump discharge. The pressurizer maintains RCS pressure within specified limits in conjunction with the chemical and volume control system (CVCS) against all normal and upset conditions without reactor trip. The pressurizer volume relative to power is increased to enhance the transient response of the RCS to reduce unplanned reactor trips. Four POSRVs are adopted instead of two SDS valves and three PSVs of the conventional plants, including OPR1000. POSRVs perform the overpressure protection for the RCS, depressurize the RCS for the initiation of a feed and bleed operation in the event of a total loss of feedwater (TLOFW), and allow remote manual operation under postaccident conditions to prevent high-pressure ejection of molten core. The outlet lines from the POSRVs connect directly to the ring-shaped section of the pressurizer discharge header, which transfers the steam/water discharge to the IRWST. This design prevents the contamination of containment by RCS coolant discharge and ensures reliable valve operation without chattering and leakage for any type of discharge flow condition (Shinkori Unit 3, 4 PSAR 2008).

Steam Generator The steam generator (SG) is a vertically inverse U-tube heat exchanger with an integral economizer, which operates with the RCS coolant in the tube side and secondary coolant in the shell side. The two SGs are designed to transfer the heat of 3,983 MWth from the RCS to the secondary system. The secondary system produces steam to drive the turbine-generator, which generates 1,400 MW of electrical power. Moisture separators and steam dryers in the shell side limit the moisture content of the exit steam to less than 0.25 w/o during normal full power operation. An integral flow restrictor has been provided in each SG steam nozzle to restrict the discharge flow in the event of a steam-line break. For the inspection and maintenance of the primary side, a 21 in. primary manway is provided in the cold leg and hot leg side of the primary head, respectively. For the secondary shell side, two 21 in. secondary manways allow access to separator, dryer area, and internal hatch over the top of the tube bundle, and two 8 in. handholes are provided for sludge lancing on the top of tube-sheet. To improve the integrity of SG tubes, the SG tubes are made of Inconel-690, which has high resistance to corrosion. The loose parts trapping feature inside of the feedwater nozzle is adopted to prevent damage to the internals and tubes of the SG by foreign materials originating from the

3	Superior neutron economy (save fuel cycle cost \$1 million/cycle)	0.374" rod diameter Axial blankets	0.382" rod diameter No axial blankets
4	High seismic capability (mid-grid dynamic buckling strength 3,400 → 4,900 lb)	High-strength straight grid strip Increased load bearing length	Low-strength straight wavy grid strip
5	Improved fuel rod fretting resistance	Large contact area with conformal surface spring and dimple Inconel top and bottom grids with optimized spring rate	Normal contact area with cantilever spring and arched dimple Zry-4 top grid and Inconel bottom grid
6	Improved debris-filtering capability	Small hole and slot bottom nozzle Protective grid with long end plug	Standard large hole bottom nozzle GUARDIAN™ grid with long end plug
7	High manufacturing productivity	Standardized fuel rod size and manufacturing process Spot welded guide tube-to-grid structure	TIG welded guide tube-to-grid structure

connected secondary system. The upper tube support bar and plate are designed to prevent the SG tube from flow-induced vibration. The SG tube plugging margin is increased by 10% (compared to OPR1000). This increases the SG tube heat-transfer area, which increases steam flow. This design improvement accommodates increased core power and compensates for the lower operating temperature of the secondary side, which is induced from the reduced core exit temperature. This design also enhances the resistance of the SG tube to stress corrosion and extends the lifetime of the SG. The water volume of the SG secondary side is enlarged to increase the dry-out time up to 20 min in the event of TLOFW. This design enhances the capability of alleviating the transients during normal operation and reduces the potential for unplanned reactor trips and enhances plant safety and operational flexibility. To improve operability, the angle of the primary outlet nozzles is modified to enhance the stability of mid-loop operation, and the SG water-level control system is designed such that the water level is controlled automatically over the entire operating range (➤ [Table 18](#)) (Shinkori Unit 3, 4 PSAR 2008).

Secondary System

The secondary system consists of the main steam, turbine generator, condensate, feedwater, extraction steam, and auxiliary systems. The heat balance of the secondary system is determined through optimization studies considering system operability, reliability, and economy. The secondary system is designed to be capable of operating at 3–6% house load for a period of at least

4 h without any detrimental effects on the systems and increasing the plant condition from a cold condition to full power within 200 min, excluding rotor preheating. The main steam supply system (MSSS) transports the steam from the steam generators to the power-conversion system and removes the heat from the RCS. The steam flow is directed from the SGs to the high-pressure (HP) turbine, of which the inlet steam pressure is maintained at 962 psia during full power. The turbine generator consists of a double-flow HP turbine and three double-flow low-pressure (LP) turbines driving a direct-coupled generator. The LP turbine rotors are of mono-block type. The material used for the LP rotors is Ni–Cr–Mo–V alloy steel and is treated to obtain enough toughness. The 52 in. last stage buckets of the LP turbine are designed to have low stress and

■ Figure 14

Integrated head assembly (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

increased stiffness. The turbine rotor is manufactured as one piece by forging to reduce the susceptibility of stress corrosion cracks (SCCs). The turbine control system is improved to enhance the reliability and maintainability by the redundant design of controllers and the strengthening of the diagnostic functions. The vibration monitoring functions are improved by strengthening the self-diagnostic functions of the detectors and multidirectional measurements. In addition, earthquake-proof structures are installed to prevent a turbine trip caused by high vibration.

The generator system consists of the generator itself and auxiliary systems such as a stator cooling water system, gas control system, and seal oil system. The stator of the generator takes a highly reliable F-class Micapal II insulation system and a highly reliable brazing technology. The rotor of the generator also adopts the highly reliable insulation system and radial flow cooling method. Static excitation type is adopted to reduce mechanical wearing. The auto-voltage regulator (AVR) is placed in a dedicated room to minimize its malfunction by protecting it from heat and humidity. Also, the filtration abilities of the stator cooling water pipelines are strengthened to not heat up by the reduced coolant flow.

The condensate and feedwater systems transfer condensate from the main condenser hotwells to the SGs, while the feedwater heaters raise the condensate temperature by using the extraction steam, and the deaerator removes the entrained oxygen and noncondensable gases. The feedwater heaters are installed in six stages and arranged horizontally for easy maintenance and reliability. The feedwater flow control system is designed to control the feedwater flow automatically over the full operation range and to operate three turbine-driven main feedwater pumps during normal power operation. When one main feedwater pump is tripped during the full power condition, the other two main feedwater pumps would be able to provide the total

feedwater flow to the full power condition. This design reduces unnecessary power cutback and unplanned turbine trip.

The configuration of the main feed water pump (MFWP) is designed to be 3×55% to allow more reliable operation. Even if one MFWP is tripped during full power condition with three MFWPs operating, the other two MFWPs could recover the total feedwater flow to the nominal value of the full power condition and the plant is restored to the full power condition. This design reduces unnecessary power cutbacks and unplanned turbine trips. The auxiliary feedwater system (AFWS) supplies feedwater to the SGs for events resulting in loss of normal feedwater and requiring heat removal through the SGs. The AFWS is actuated by an auxiliary feedwater actuation signal (AFAS) from the ESFAS or the diverse protection system (DPS). The ESF-component control system (ESFCCS) includes logic to close the flow-control valves when the SG water level has risen above a high-level set point and to reopen this valve when the SG water level drops below a low-level set point. Different from the conventional plant, the AFW storage tank is installed in the auxiliary building separated from the condensate tank to enhance the system reliability in transients (➤ [Table 19](#)).

MMIS and Electrical System

I&C System In order to come up with high performance and maintainability, I&C systems including control and monitoring systems are based on proven, diverse, and commercial off-the-shelf hardware, network, and software platforms such as DCS and programmable logic controller (PLC) with operating experience of more than 3,000 years. The I&C architecture consists of two platforms. One is a safety grade PLC platform, which is comprised of core protection

■ Figure 15

Main control room (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

calculator (CPC), plant protection system (PPS), and ESF-component control system (ESF-CCS). These safety systems are designed to meet the licensing requirements for independence, defense-in-depth, diversity analysis, failure mode analysis, and environmental qualification. The fail-safe concept is implemented such that the system is allowed to operate safely. The other is a non-safety-grade DCS platform, which consists of PCS, NSSS process control system (NPCS), process-component control system (P-CCS), DPS, and information processing system (IPS). The DCS with multi-loop controllers is adopted for these non-safety I&C systems. The number of I&C platform is minimized to increase the cost-effectiveness and to decrease operator's maintenance burden. Defense against the common mode failure (CMF) of digital plant protection systems is one of the key requirements in designing digital I&C systems. The DPS is designed to be diverse from the PPS against the CMF of the digital plant protection system. Diverse manual ESF actuation is also designed to keep the plant safety against severe situations due to a simultaneous digital system failure of the PPS and the DPS. The open architecture concept is applied to the configuration of the I&C system for high reliability and maintainability. In addition, the stringent software and hardware qualification process is established and followed for the life cycle.

Main Control Room The computerized MCR of APR1400 adopts compact workstations (► Fig. 15). These workstations are integrated with operator support systems with a human-centered automation concept. The MCR provides operating crews with an information-oriented operational environment that enables fast situational awareness of plant status. The design goal of the advanced MCR is to enhance the plant safety by extending operator coping time against accidents and to reduce human errors by improving the operational readiness. The following advanced technologies and design concepts are being incorporated to achieve the design goal. In addition, a safety console is provided in the MCR as a backup facility for safe operation against a total failure of workstations.

Compact Workstation The MCR contains workstations, a large display panel (LDP), and a safety console. The workstations are identical and reconfigurable so that an operator has a backup workstation to cope with the situation when different types of workstation failures are encountered. The workstations are placed near one another in a fixed location to improve communication among the operators. A unified computer-based MMI design is applied for all the major plant systems for operator's convenience. The compact workstation with a computer-based MMI reduces the interface management tasks using the two-click access and format chaining. The MMI design adopts the system- and function-based displays as well as the diverse information displays for operation. The enhanced display includes dynamic logic display, P&ID, video data from CCTVs, and design data. In addition, the compact workstation is designed to provide all operational means, including the computerized operator support functions, such as critical function monitoring, success path monitoring, signal validation, and computerized procedures. This integrated compact workstation design is expected to reduce workload of the operating crew.

Large Display Panel The LDP is large enough to be viewed from anywhere in the MCR. It presents the plant-level indications and alarms, which enable the operating crews to assess the plant situation related to the critical safety and the power production functions. The LDP displays are developed to have a simplified and fixed format with the 'dark board' concept. A 'dark board' concept means that no alarm indicates the normal state of plant. This allows operating crews quickly and easily to assess the plant status at a glance. The LDP is designed to quickly direct the operators' attention to the exact trouble source and to allow them to diagnose the severity of the plant incidents. The LDP provides sufficient information for emergency operations. The LDP also continuously displays the critical function performance and the success path availability.

Safety Console The safety console is provided as a backup for safe operation against a total DCS failure. The safety console indications are designed to provide qualified information and alarms in a similar format to the LDP display to enhance familiarity of the display.

Computerized Procedure System The computerized procedure system (CPS) provides an integrated presentation of procedural instructions and related process information needed to execute applicable procedures by both an operator and the operating crews. The CPS also monitors the plant condition and supports the recovery actions for inadvertent errors committed by operators. The CPS is designed to monitor continuously applied steps and nonsequential steps. The CPS supports the multiple procedure execution as well as the multiuser execution. The CPS is capable of accessing information displays and alarm systems and evaluating the instruction logic of a procedure.

Human Factors Engineering The extensive HFE program is incorporated to reduce the possibility of a human error in the MCR. In the conceptual and basic design at the R&D stage as well as during the construction phase of the plants, the MMI design has been analyzed and evaluated in an iteratively expanding manner with participation of more than 100 licensed operators and human factors specialists to optimize the design. During the APR1400 development, the evaluation for the MMI design has been performed seven times with full-scope dynamic mockups and an APR1400-specific dynamic mockup. The evaluation verified that the MMI are suitable

for the human factor principles and guidelines. The new MCR design was also validated to support the normal and emergency operations appropriately.

Electrical System The plant electrical system consists of the generator, the generator circuit breaker, the main transformer (MT), the unit auxiliary transformers (UATs), and the standby auxiliary transformers (SATs). The normal power sources for non-safety loads are the off-site power through the main transformer and the on-site power through the UATs from the generator. The electric power for the safety-related systems is supplied from the following four alternative ways: (1) the normal power source of the normal off-site power through the MT or the on-site power through UATs generated by the in-house generator, (2) the standby off-site power connected through the SATs with the grid, (3) the on-site standby power supply from two EDGs, and (4) an alternative alternate current (AAC) source from a backup diesel generator. During normal operation, the electric power for the safety-related systems is supplied from the normal power source of the normal off-site power through the MT or the on-site power through the UATs. If the normal power source is not available, the safety loads are covered with the off-site power source via the SATs. Then, if the off-site power source to the safety-related systems is interrupted, the safety loads are backed up by two independent Class 1E EDG sets. Each of them is located in a separated room of the auxiliary building and is connected to two 4.16 kV safety buses. The nonclass 1E AAC source adds more redundancy to the electric power supply for safety systems. It is provided to cope with SBO situation, which has a high potential of transients to severe accidents. The AAC source has sufficient capacity to accommodate loads on the safety (➤ Fig. 16).

Figure 16

One line diagram of station power block (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

1.3.2 Major Safety Design Features

Safety

Goals and Design Philosophy One of the APRI400 development policies is to dramatically increase the level of safety (APRI400 SSAR 2002). The following safety goals are established to improve the plant safety level by ten times. The APRI400 design has been made to meet these safety goals with securing an additional margin of safety to protect the owner's investment as well as public health (Kim et al. 2005).

The major safety goals of APRI400 (KURD 1998) are as follows:

1. The total CDF shall not exceed 10-5/RY for both internal and external initiating events and 10-6/RY for a single event and an incident occurring in a high-pressure condition.
2. The containment failure frequency shall be less than 10-6/RY.
3. The whole body dose at the site boundary shall not exceed 0.01 Sv (1 rem) for 24 h after the initiation of core damage with a containment failure.

Safety Systems and Features The safety systems consist of SIS, IRWST, safety depressurization and vent system (SDVS), containment spray system (CSS), and AFWs (► Fig. 17). The main design concept of the SIS is simplification and redundancy to achieve higher reliability and better performance than the conventional plant. The SIS is comprised of four independent mechanical trains without a tie line among the injection paths and two electrical divisions. Each train has one active SIP and one passive safety injection tank (SIT) equipped with a fluidic device (FD). For simplicity and independence of SIS, the common header installed in the SIS lines of the conventional plant is eliminated (Kim et al. 2000).

This design separates the functions of SIS and shutdown cooling system (SCS) (► Fig. 18). The passive flow regulator, that is, the FD is installed in the SIT. The basic concept of the FD is vortex flow resistance. When water flows through the stand pipe, which is installed in a rectangular direction with the exit nozzle, it creates low vortex resistance and a high flow rate. When the water level is below the top of the stand pipe, inlet flow is switched to the control ports that are installed in a tangential direction with the exit nozzle, and it makes a high vortex resistance and low flow rate. Thereby, the SIT discharges a large amount of water to fill the reactor vessel lower plenum rapidly when water level is above the stand pipe. However, when the water level is below the stand pipe, the SIT injects a relatively small amount of water for a long time. The FD installed in SIT substitutes for the low-pressure SIPs such that the low-pressure SIP is eliminated.

The IRWST is located inside the containment and the arrangement is made in such a way that the injected emergency cooling water returns to the IRWST. This design removes the operator action of switching the suction of SIP from the IRWST to the containment recirculation sump, required in the conventional plant. This new design lowers the susceptibility of IRWST to external hazards. The IRWST provides the following functions: storing refueling water, a water source for the SIS, shutdown cooling system, and containment spray system, a heat sink to condense steam discharged from the pressurizer for rapid depressurization if necessary. This prevents high-pressure molten corium ejection and enables feed and bleed operation. This also allows supplying coolant to the cavity-flooding system, which mitigates molten corium concrete interaction in severe accidents. By adopting the advanced features of the FD in SIT and the IRWST, the high-pressure injection, low-pressure injection, and recirculation modes of the conventional SIS are merged into one operational mode of safety injection. The SIS is designed

■ Figure 17

Fluidic device (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

for safety water to be injected directly into the reactor vessel so that the discharge of injected flow through the broken cold leg is eliminated. The SDVS is a dedicated safety system designed to provide a safety grade means to depressurize the RCS in the event that the pressurizer spray is unavailable during plant cooldown to cold shutdown and to rapidly depressurize the RCS to initiate the feed and bleed method of plant cooldown subsequent to the total loss of feedwater event (Kwon et al. 1997). The POSRVs are employed for feed and bleed operation. This system establishes a flow path from the pressurizer steam space to the IRWST. The CSS consists of two trains and takes the suction of its pump from the IRWST to reduce the containment temperature and pressure during accidents occurring in the containment. The CSS is interconnected with the SCS, which is also comprised of two trains. The pumps of these systems are designed to have the same type and capacity. This design makes the CSS have a higher reliability compared with the conventional plant. The AFWs consists of two divisions and four train systems and supplies feedwater to the SGs for RCS heat removal in the case of loss of main feedwater. In addition, the AFWs refills the SGs following a LOCA to minimize leakage through preexisting tube leaks. The reliability of AFWs has been increased by the use of two 100% motor-driven pumps, two 100% turbine-driven pumps, and two independent safety-related emergency feedwater storage tanks located in the auxiliary building instead of a condensate storage tank of the conventional plant.

Seismic Design The buildings and structures are designed with the application of the SSE criterion of 0.3 g as a design basis earthquake (DBE) to increase their ductility against earthquakes.

Figure 18

Safety injection system (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

The seismic input motion enforced in the high frequency range is applied to envelope the design ground response spectrum of the Regulatory Guide 1.60 standard spectrum. The design load of operating base earthquake (OBE) is eliminated to improve design and verification according to 10 CFR 50 Appendix S. Since the seismic evaluation is performed with the inclusion of the effects of soil–structure interaction on soil sites, the APRI400 can be constructed on rock bed sites as well as on soil sites (KURD 1998).

Severe Accident

Reactor Containment Building Design In order to maintain the integrity of the RCB and to prevent the leakage of radioactive materials during SAs, the RCB is designed to have free volume large enough so that the structural load is maintained below the ASME Section III Service Level C for 24 h after SAs. This also helps keep hydrogen concentration under 13% in case of 75% oxidation of fuel clad steam. Another design feature to prevent leakage is installation of the 0.25 in. steel liner plate on the inboard side of the RCB. In addition, the RCB is constructed with the prestressed concrete having the high compressive strength of 6,000 psi after 91 days of curing. The reactor vessel cavity is designed such that molten core materials spread out for its heat transferable area to be not less than $0.02 \text{ m}^2/\text{MW}$ and is cooled to solidify on the cavity floor. Also, the convoluted vent path of the reactor vessel cavity prevents the molten core debris from releasing to the containment atmosphere.

Mitigation Systems The SAs management system prevents and mitigates SAs, and maintains containment integrity. It is designed to meet the procedural requirements and criteria of US NRC regulations, including the post Three Mile Island (TMI) requirements for new plants as reflected in 10 CFR 50.34 (f) and SECY-93-087. This system includes a large dry prestressed concrete containment, hydrogen management system (HMS), large reactor cavity and core debris chamber, cavity flooding system (CFS), In-vessel corium retention through external reactor vessel cooling system (IVR-ERVCS), SDVS, emergency containment spray backup system (ECSBS), and severe accidents management procedure (SAMP) (KURD 1998).

Hydrogen Mitigation System The HMS consists of 26 PARs and 10 glow plug igniters. The capacity of the HMS is designed to accommodate the hydrogen production from 100% metal–water reaction of fuel cladding and to limit the average hydrogen concentration in containment below 10% in accordance with 10 CFR 50.34 (f) for a degraded core accident.

Reactor Cavity Design The reactor cavity adopts a core debris chamber, which is designed to have heat transfer area of corium more than $0.02 \text{ m}^2/\text{MWth}$. The flow path of the reactor cavity is convoluted to hinder the transfer of core debris to the upper containment. This design prevents DCH due to core debris.

Cavity Flooding System The APRI400 has two strategies for cooling the molten core: ex-vessel cooling (EVC) and in-vessel retention (IVR). The CFS supplies the coolant for ex-vessel cooling. It consists of two trains connected with IRWST and two isolation valves that are installed in each line. When the two isolation valves are open during the SAs, the cavity cooling water is supplied from the IRWST to the reactor cavity by the gravity. It cools down the core debris in the reactor cavity, scrubs fission product releases, and mitigates the MCCI (Kim et al. 1992).

In-Vessel Corium Retention through External Reactor Vessel Cooling System

IVR-ERVCS retains molten core in the reactor vessel by cooling the external surface of the reactor vessel (► Fig. 19). This system submerges the reactor vessel bottom head before molten core relocates to the bottom head. Cooling water is supplied from the IRWST by a shutdown

■ Figure 19

Cavity flooding system and IVR-ERVCS (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

cooling pump (SCP) and a boric acid makeup pump (BAMP). This system maintains the reactor vessel integrity and reduces the threat of containment integrity.

Emergency Containment Spray Backup System The ECSBS provides long-term coolability by supplying spray water to containment for 48 h so that the containment temperature and pressure are reduced during the SAs. This system consists of spray nozzle, piping, and containment penetration. Spray water is supplied by external pump from temporary external water source. The ECSBS contributes to relieving the threat of containment integrity.

Proven and Evolutionary Technology

In order to enhance safety, operational convenience, and maintainability, the APRI400 was developed by adopting advanced design features. These advanced design features are based on the proven nuclear power plant design technology gained through many years of repeated constructions and extensive operation experiences of the OPRI1000 (see [Fig. 1.2](#)). The new design features have been successfully evaluated to ensure that they enhance the performance and safety of the APRI400. The following relevant experimental studies have been conducted over the several years by Korea Atomic Energy Research Institute (KAERI) in support of the APRI400 design.

Safety Injection Performance Test for Direct Vessel Injection

The safety injection (SI) nozzles in the APRI400 are located in the upper part of the reactor pressure vessel (RPV) downcomer. Due to this design feature, in a LOCA, the thermal-hydraulic phenomena in the RPV downcomer differ from those in the case of cold leg injection (CLI) design, and this difference is believed to govern a large break loss-of-coolant accident (LBLOCA) reflood phase (Cha and Jun 1994, Cho [1997](#)).

In order to evaluate the emergency core coolant (ECC) bypass during the reflood phase of a postulated LBLOCA and to assess the contribution of the new SI system to safety enhancement, the performance of the SI system was examined by using the multidimensional investigation in downcomer annulus simulation (MIDAS) facility ([Figs. 20](#) and [21](#)). The MIDAS facility was designed to be one-fifth length scale of the APRI400 and to use steam and water as test fluids at 190 psia and 572°F as design conditions (Kim [1994](#)).

Performance Test for Fluidic Device in Safety Injection Tank

The APRI400 uses an FD that is installed inside a SIT as a passive design feature to ensure effective use of the SIT water. This design feature enables the APRI400 to achieve the goals of minimizing the ECC bypass during a blowdown, and of preventing a spillage of excess ECC water during the refill and reflood phases of a LBLOCA. The FD provides a high discharge flow rate of SI water when the FD starts to operate, which is required during the refill phase of a LBLOCA. When the refill phase is terminated, the discharge flow rate of the SI water drops sharply but is still large enough to remove any decay heat during the reflood phase. Because of the strong vortex motion in the FD, the pressure-loss coefficient of the low flow rate period is almost ten times higher than that of the high flow rate period. The difference in the pressure drop helps extend the total duration of the SI and also allows the low-pressure safety injection pump to be removed from the SI system. In order to confirm the performance of the FD designs, full-scale performance tests were carried out in the valve performance evaluation rig (VAPER) facility, which was designed with the same size and operating conditions as those

■ Figure 20
MIDAS facility (Courtesy of Korea Atomic Energy Research Institute)

■ Figure 21
Schematic diagram of MIDAS facility (Courtesy of Korea Atomic Energy Research Institute)

■ Figure 22

VAPER facility (Courtesy of Korea Atomic Energy Research Institute)

of the APRI400 SIT. It was verified from these full-scale tests that the performance of the FD satisfies the standard design requirements of the APRI400 (► Fig. 22) (Kim et al. 2000).

Performance Test for IRWST Sparger To cope with transients such as a RCS overpressure, the SDVS, which enables feed and bleed operation, and the SIS are incorporated in the APRI400 to maintain the integrity of the RCS and the core. Actuation of POSRVs results in a transient discharge flow of air, steam, or a two-phase mixture to the IRWST through the spargers (IRWST T/H Load Analysis 1996).

The discharge of these fluids induces complicated thermal-hydraulic phenomena such as water jet, air clearing, and steam condensation (► Figs. 23 and ► 24). These phenomena impose hydrodynamic forces on the IRWST structure and the components of the SDVS. These structures shall be designed so as to withstand these hydrodynamic loads and to maintain their structural integrity as well as the safety functions of the engineered safety features systems. The hydrodynamic loads on the IRWST wall and the components of SDVS are induced by air clearing and steam jet discharge through a prototype sparger of the APRI400. The relevant tests of these loads were conducted at the blowdown and condensation (B&C) facility.

Advanced Thermal Hydraulic Test Loop for Accident Simulation

The advanced thermal hydraulic test loop for accident simulation (ATLAS) (► Figs. 25 and ► 26) is a thermal hydraulic integral effect test facility constructed at Korea Atomic Energy Research Institute (Baek et al. 2005). It was used for simulations of various transients and accident conditions of the APRI400 and the OPR1000. It simulates various accident scenarios at actual pressure and temperature conditions of the APRI400. The integrated safety of the APRI400 with new design features has been verified through accident simulation in the ATLAS (Baek et al. 2009). The major accident scenarios are reflood phase of the LBLOCA, small-break LOCA scenarios including the DVI line breaks, steam generator tube ruptures, main steam line breaks, feedwater line breaks, mid-loop operation, and other transient conditions.

1.4 Operation and Construction

1.4.1 Status of Operation

KHNP is the largest of the six power-generation subsidiaries created from Korea Electric Power Corporation (KEPCO) in April 2001. In terms of installed capacity and gross power generation, nuclear power in Korea constituted 27% and 39%, respectively, as of 2006. This high attribution ratio of nuclear power generation results from the fact that nuclear power plants are base load plants in Korea, which maintain high capacity factor.

■ **Figure 25**
Schematic diagram of ATLAS (Courtesy of Korea Atomic Energy Research Institute)

KHNP has made great strides in achieving capacity factor over 90% (as high as 100% for Yonggwang Unit 3 in 2005) and one cycle trouble free (OCTF) operation (as long as 482 days for Ulchin Unit 3). The outstanding performance exceeding the global average could be attributed to the excellent operation and maintenance techniques accumulated for the last 30 years (► [Fig. 27](#)).

Due to the high operability and maintainability that come from the operational characteristics and design improvements of OPR1000, OPR1000 units have shown excellent operational performances: high capacity factor, short maintenance period, reduced reactor scram, high thermal efficiency, and reduced radiation exposure and radwaste (► [Tables 20–22](#)).

1.4.2 Construction

A new construction schedule and constructability-enhancement methods were developed based on the experience gained from repeated OPR1000 constructions. The power block

Figure 26

ATLAS facility (Courtesy of Korea Atomic Energy Research Institute.)

foundation of APRI400 is seismically enhanced with the application of 0.3 g SSE criterion as a DBE. The RCB and the AB are built on a common basemat. This design requires a highly increased mat size and the amount of concrete. Thus, the construction method for this massive concrete structure is reviewed to meet the target duration. The common basemat foundation is simplified as a flat type so that it may benefit the concrete works. Modularization has been introduced to reduce the construction period and the cost. There are three types of modules: the structural, mechanical equipment, and composite modules. To expand the modular construction, the research is being done for the steel-plate concrete (SC) structure module, the mechanical equipment, and the composite module. If the composite module is applied to all buildings in the nuclear power plant, the construction time will be dramatically reduced to less than 40 months through prefabrication at both the factory and the site (➤ [Table 23](#)).

Reactor Containment Building Work

There are two ways to bring big components such as steam generators into the RCB and to place them in the proper locations. One is the over-the-top method (OTM), in which massive equipment is placed into its proper position through the top of the RCB by a large capacity crane. The other is the conventional side method (SM), in which major components are brought into the RCB through an equipment hatch and positioned with a polar crane in containment. Since

Figure 27
Supply mix (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

the SM requires two steps, it takes longer. Since the RCB is wrapped around the AB and has bigger and heavier components than those of conventional nuclear power plants, the OTM is favorable for the installation of major components. To reduce the construction time, the OTM has been adopted after a comparative study and assessment. The detailed installation procedure has been verified through simulation by using three-dimensional computer-aided design (3-D CAD) models to confirm its feasibility (➤ Fig. 28).

Modularization

To reduce the construction time, fabrication work at the factory for mechanical and electrical equipment needs to be increased. Approximately 80 items of the APR1400, including auxiliary and containment building water chillers and pumps, feedwater pumps and turbine drives, charging pumps, turbine building component cooling water heat exchangers, and condensers, have been identified to be suitable for modularization. Reactor internal assembly is manufactured into three pieces in the conventional plant: core support barrel (CSB), the lower support structure (LSS) with core shroud, and the UGS. The assembling of reactor internals at the construction site takes a long time and is on the critical path of the construction schedule. Reactor internals of the APR1400 are fabricated into two parts by integrating the CSB, LSS, and CS. This modularization of reactor internals is estimated to reduce the construction time by approximately 3 months. In the condenser modularization, three shells and transitions are assembled in the factory, and the low-pressure feedwater heaters and the water boxes are assembled at the construction site.

■ Table 20

Capacity factors^a of OPR1000 in 2001–2007

Unit	Year							Commercial operation date
	2001	2002	2003	2004	2005	2006	2007

Average	94.7	95.7	96.7	89.7	95.7	91.4	91.6	

$$^a \text{Capacity factor} = \begin{cases} \frac{\text{Total MWh gross}}{\text{Capacity MW gross} \times 8,760 \text{ h}} \times 100 \% & \text{for } 2001-2005 \\ \frac{\text{Total MWh gross}}{\text{Recent three years average generation output MW} \times 8,760 \text{ h}} \times 100 (\%) & \text{for } 2006-2007 \end{cases}$$

APR1400 Construction Schedule

Along with the many new construction methods, the modularization technologies of reactor internals and the mechanical and structural composites have been applied to the construction of APR1400. The OTM allows the major components in the containment to be manufactured as large modules and installed in the early phase of construction. The modular construction method is applied to the containment liner plate (CLP) and stainless steel liner plate (SSLP) to reinforce the steel and the structural steel module. This method is also applied to the fabrication of equipment such as the reactor internals and the condenser. The deck plate construction method is applied to the construction and the installation of mechanical and electrical equipment to be carried out simultaneously in the auxiliary building and compound building. The first two units in APR1400 fleet (Shinkori 3&4) commenced construction in 2007. It is estimated that Shinkori 3&4 will be constructed in less than 51 months for the first unit and 45 months for the second unit. The succeeding units are expected to be constructed in 40 months (🔍 Fig. 29).

2 CANDU Reactors in the Republic of Korea

2.1 Introduction

In addition to the main fleet of light water pressurized water reactors (PWRs), Korea has installed Canadian pressurized heavy water reactor (PHWR) CANDU6's as a complementary reactor type. Korea Hydro and Nuclear Power (KHNP) began to operate the first CANDU

unit (Wolsong 1) in 1983, and three additional units (Wolsong 2, 3, 4) in 1997, 1998, and 1999, respectively. ➤ [Table 24](#) provides a list of Canadian design nuclear power plants. ➤ [Table 25](#) shows the construction and operation phases of CANDU reactors in Korea (Wolsong Unit 3, 4 FSAR, 2003).

2.2 System Description

2.2.1 CANDU Reactor Model

Among the several types of heavy water reactors considered worldwide, the dominant type is the heavy water cooled, heavy water moderated pressure tube reactor developed in Canada (Heavy Water Reactors, 2002). This type of reactor is designed to use natural uranium, but it can also use slightly enriched uranium or a variety of other fuels. Typically, the reactor core is contained in a cylindrical stainless steel tank (calandria), which holds the heavy water moderator at low temperatures ($<80^{\circ}\text{C}$) and low pressure ($\sim 0.1\text{ MPa}$).

➤ [Figure 30](#) shows a schematic of CANDU6 reactor. ➤ [Figure 31](#) shows a cross-section of CANDU6 calandria. The calandria houses fuel channels that span horizontally and it also houses reactivity mechanisms that span vertically. The calandria shell is a horizontal, single-walled cylinder made of austenitic stainless steel. The ends of the calandria shell are enclosed

by stainless steel tube-sheets, which form a common boundary between the calandria and the end-shields.

The heavy water moderator in the calandria is a unique feature in CANDU reactors, which provides a passive heat sink for some accident scenarios. A cover gas system maintains a pressure of less than 27.6 kPa (4 psia) above the moderator.

The CANDU6 reactor core has 380 fuel channels. Each fuel channel consists of a zirconium/niobium alloy pressure tube surrounded by a zircaloy-2 calandria tube with CO₂ gap (annulus gap) in between. Inside each pressure tube, the heavy water coolant (separated from the heavy water in calandria) flows through the fuel channel to remove the heat produced by fission of the natural uranium fuel. Each fuel channel contains 12 fuel bundles. The fuel bundles are made up of 37 Zircaloy-4 tubes containing natural UO₂ pellets. ➤ [Figure 31](#) also shows a fuel bundle.

Over-the-top method (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

2.2.2 Primary Heat Transport System (PHTS)

The primary heat transport system is comprised of two loops. Each loop serves 190 of the 380 reactor fuel channels. Each loop contains two pumps, two steam generators, two inlet headers, and two outlet headers in a “figure-of-eight” arrangement (Fig. 32). Feeders connect the inlet and outlet ends of the fuel channels to the inlet and outlet headers, respectively. Pressurized heavy water circulates through the reactor fuel channels to remove the heat produced by fission. The heat is transported by the reactor coolant to steam generators where it is transferred to light water to generate steam, which subsequently drives the turbine generators. The steam

■ Figure 29

APR1400 construction schedule (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

generators, PHTS pumps, and headers are located above the reactor, permitting the heat transport system coolant to be drained to the head elevation for maintenance of the PHTS pumps and steam generators, and also facilitating thermosyphoning (natural circulation) when the PHTS pumps are unavailable and the reactor is shut down.

The two closed loops are generally interconnected with isolation valves. An automatic loop isolation reduces the rate of reactor coolant loss in the event of a loss of coolant accident. The isolating valves are automatically closed when the PHTS pressure drops to below certain set-point pressure whether or not a loss of coolant accident (LOCA) has occurred and whether or not the emergency core cooling system (ECCS) is actuated. The reactor outlet headers at one end of the reactor are connected to a common pressurizer. The pressurizer is the principal component for pressure control of the heat transport system.

2.2.3 Moderator System

The heavy water moderator in the calandria is used to thermalize fast neutrons produced by fission. The heavy water moderator is circulated through the calandria and moderator heat

Wolsong 4	1990	1991	1999	700

exchangers to remove the heat generated in the moderator during reactor operation. The moderator heat is in turn rejected to the recirculated cooling water system. The operating pressure at the moderator free surface is slightly above atmospheric.

The moderator system is fully independent of the primary heat transport system (► Fig. 33). The moderator system includes two 100% pumps and two 100% tube and shell heat exchangers.

■ Figure 30

A Schematic of a CANDU6 PHWR (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

The moderator system head tank maintains the moderator level in the calandria within the required range by accommodating moderator swell and shrink resulting from temperature fluctuations. The heavy water in the calandria functions as a heat sink in the unlikely event of a loss of coolant accident coincident with failure of the ECCS. The capability of this heat sink is assured by controlling the heavy water temperature in the calandria within specified limits.

2.2.4 Emergency Core Cooling System (ECCS)

The function of the ECCS is to provide an alternate means of cooling the reactor fuel, in the event of a LOCA, which depletes the normal coolant inventory in the PHTS to an extent that fuel cooling is not assured.

■ Figure 31

Cross-section of CANDU6 calandria (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

There are three stages of ECCS operation according to the operating pressure: high, medium, and low pressure. As soon as the PHTS header pressure drops to below 4.04 MPa(g) (586 psig), water flows from the high-pressure ECCS tanks into headers of the failed loop. Although the flow rate from the water tanks depends on the break size, the high-pressure injection lasts for a minimum of 2.5 min for a 100% header break size.

The medium pressure injection valves open when the low high-pressure ECC water tank levels signal on. The ECC pump injects water from the dousing tank to all reactor headers when the pump discharge pressure is higher than the reactor header pressure. The medium pressure injection lasts for a minimum of 12.5 min for a 100% header break size.

As the dousing tank water depletes, the medium pressure injection is automatically terminated and low-pressure injection starts. Long-term low-pressure injection is provided by collecting the mixture of H_2O and D_2O from the reactor building sump and recirculating it

Emergency core cooling system (ECCS) of a CANDU6

into the PHTS via the emergency cooling system heat exchangers. The low-pressure ECCS circuit is designed to operate at least 3 months following a LOCA. ➤ [Figure 34](#) shows a simplified diagram of the ECCS. For large breaks, the ECCS recovery heat exchanger is the main heat sink. For small breaks, the steam generator continues to be the main heat sink.

2.2.5 Shutdown System

The CANDU6 reactor uses two diverse, passive, shutdown systems that are independent of each other and from the reactor regulating system. Each shutdown system is capable of tripping the reactor and has sufficient negative reactivity to maintain it in a shutdown state. Especially even if any class of electrical power fails, shutdown system has no effect in tripping the reactor.

Shutdown system No.1 consists of mechanical shutdown rods, which drop into the core when a trip signal de-energizes clutches that hold them out of the core (➤ [Fig. 35](#)). Shutdown system No.2 injects a concentrated solution of gadolinium nitrate into the low-pressure moderator to quickly render the core subcritical. The injection is initiated by opening fast acting valves to pressurize the individual poison tanks associated with each of the injection nozzles with helium.

2.2.6 Containment System

The major function of the containment system is to confine the release of fission products into the environment during accident to within the acceptable limits. The containment system

■ Figure 35

Shutdown system (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

consists of a leaktight envelope around the reactor and associated nuclear systems, and includes containment isolation systems, containment atmosphere energy removal systems, and cleanup systems.

The CANDU6 single unit containment is a prestressed concrete building consisting of three principal structural components: a base slab, a cylindrical wall, and a spherical segmental dome. The concrete provides strength and shielding. The inner surface of the reactor building is lined with an epoxy coating, instead of steel plate, to improve leaktightness (● Fig. 36).

The spray dousing system is designed to limit the magnitude and duration of containment overpressure caused by a LOCA or a main steam line break inside the reactor building. The system is automatically initiated when the containment pressure exceeds 14 kPa (2 psig). The flow rate is designed to limit the maximum building pressure to less than the design pressure following a guillotine rupture of the heat transport system header. When containment pressure decreases to 7 kPa(g) (1 psig), the dousing valves close in 7 s. According to the size of the break, there is a continuous or cyclic operation of dousing valves. Manual operation of the dousing system is possible from either control center.

In recent CANDU6 plants such as Wolsong 2, 3, and 4, a network of hydrogen igniters is provided to burn any local concentrations of hydrogen formed in the long-term post-LOCA and

■ **Figure 36**
Single unit containment (Courtesy of Korea Hydro and Nuclear Power Co., Ltd.)

in dual failures (LOCA plus loss of ECCS), preventing hydrogen from reaching deflagration or detonation levels by using controlled ignition as soon as the hydrogen concentration reaches flammable limits.

2.3 Major Safety Design Features

The inherent safety features available in the CANDU concept are provided by various engineered safety features built into the design. This section discusses the principles followed for the design of engineered safety features in CANDUs and provides a description of some of the salient features. In the engineering of the systems, well-established safety design principles and guidelines are followed, some of which are uniquely applied to CANDUs. These are highlighted below.

2.3.1 Defense in Depth

The defense in depth principle is, of course, not unique to CANDUs. In following the principles of defense in depth, emphasis is placed on minimizing the challenges to the lower echelons. Accident prevention is similar to that employed for other reactor types and, with one exception, will not be described in detail here. In fact, many of the events of moderate frequency can be handled by normal operating or process systems without needing to invoke any of the safety systems; for example, many deviations and transients can be safely handled by the reactor set back that reduces reactor power at a predetermined rate through the reactor regulating system. Small leaks from the HTS, such as those from breaks in instrument tubing, which are within the capacity of the D₂O feed pumps, can be handled by operator actions to shut down the reactor and actuate the small leak handling system.

One particular aspect of defense in depth in pressure tube CANDUs is the application of “leak before break” to the pressure boundary of the core (the pressure tubes). The critical crack length is well above the crack length at which leaks occur; such leaks are detected through an annulus gas system that monitors the gas between the calandria tube and the pressure tube in each fuel channel. The operator can then shut down and depressurize the reactor long before a rupture occurs.

Leak before break can be prevented by the occurrence of excessive local zirconium hydride concentrations in the pressure tube, resulting from, for example, pressure tube/calandria tube contact. Zirconium–niobium does not hydride as fast as Zircaloy-2, but separation must still be maintained between the pressure tube and the calandria tube. In current CANDUs, the pressure tube/calandria tube gap and pressure tube hydride concentration are carefully monitored to ensure that all known pressure tube failures would be signaled beforehand by a leak.

Two Group Concept

In order to protect the plant against common mode incidents such as fires and missiles, the safety systems have been divided into two groups that are functionally and physically independent of each other and which use diverse and independent support systems such as electrical power and service water. Each group has the capability to

- Shut down the reactor,
- Remove decay heat from the fuel,
- Minimize the escape of radioactivity,
- Monitor the safety status of the plant.

Group 1 comprises

- Normal plant operating systems, including the reactor regulating system, all process systems (except for the moderator cooling) and the main control room
- SDS 1 and the ECCS.

Group 2 comprises

- An emergency power supply,
- An Emergency Water Supply (EWS),
- SDS2 and containment systems,

■ Table 26

Required safety functions of Groups 1 and 2

Required safety function	Mechanism employed	
	Group 1	Group 2
	SDS 1	SDS 2
Shutdown of the reactor	Steam generator cooling or shutdown cooling or ECCS	Cooling by EWS or firewater through the steam generator and moderator cooling
Removal of decay heat		
Minimization of radioactivity release	Decay heat removal via the steam generators or shutdown cooling or ECCS	Containment system
		Hydrogen ignition system (on recent HWRs)
Monitoring of the safety status of the plant	Main control room	Secondary control area and local panels/controls

This allocation of systems to groups is typical of most CANDUs. However, in the CANDU9 design, the ECCS is Group 2 system and containment systems are Group 1, allowing for a simplified layout.

- Emergency moderator cooling and circulation,
- A secondary control area or supplementary control room.

The EWS is plant dependent; in most CANDUs it consists of a portion of the dousing tank water and/or an external water reservoir, with pumps powered by the emergency power supply. The required safety functions and the systems in each of the two groups to satisfy these functions are shown in ► [Table 26](#).

Redundancy

In line with the usual practice for nuclear power plants, adequate redundancy is provided in safety systems such that the minimum safety functions can be performed even in the event of failure of any single active component in the system. Over and above this “single failure criterion,” safety systems in CANDUs are also required to meet specified unavailability targets, the evaluation of which takes into account the maximum permissible downtime of the equipment (specified in station technical specifications for operation) due to maintenance, etc.

Separation

Physical and functional separation is ensured between each safety system and any process system, so that a failure in a process system does not impair the safety systems that are intended to protect against it or to mitigate it. As far as is practicable, this separation is also provided between different safety systems, as well as between redundant components within a safety

system. These features ensure that a single local event (i.e., fire, missile impact, pipe failure) will not result in multiple component or system failures, and that the functions required for the safety of the reactor will not be impaired.

Fail-Safe Feature

In order to minimize the probability of unsafe failures, wherever possible, the logic and instrumentation circuits are designed to fail in the safe direction. The limitations of this concept are due to not always being possible to define a unique fail-safe position (e.g., HTS liquid relief valves) and also because a system that requires powered operation cannot be fail-safe on loss of power. Thus, systems that are mostly passive, such as the shutdown systems and the containment isolation systems, are fail-safe on loss of control power, but the ECCS pumps rely on electrical power to operate.

2.3.2 Availability

The four CANDU safety systems, sometimes termed special safety systems (i.e., SDS1, SDS2, ECCS, and containment), are designed to meet numerical availability targets, typically 0.999 for the most recent CANDUs. This availability must be demonstrated during plant operation by periodic testing. The safety systems must be designed to permit such testing without negative impact on operations.

2.4 Status of Operation

In Korea, Wolsong Unit 1, which is the first heavy water CANDU reactor with 678MW of generation capacity was constructed with a turnkey contract in 1983. Wolsong Unit 2, 3, and 4, with 700 MW of generation capacity were constructed and started commercial operation respectively in 1997, 1998, and 1999. In the year of 2008, these heavy water CANDU reactors generated 23,006,763 MWh electricity in total. ➤ [Table 27](#) shows statistics on capacity and availability factors of CANDU reactors in operation in Korea (Nuclear Power Generation White Paper, 2009).

2.5 Spent Fuel Storage Facility

The simple fuel design of CANDU offers many benefits in spent fuel handling, storage, and disposal. Over 20 years of experience gained in the development and application of medium-term storage have resulted in technology that is well proven and economical, and which has a high degree of public and environmental protection. In fact, both the short-term (water pool) storage and medium-term (dry canister) storage of spent HWR fuel are lower in terms of cost per unit of energy than for other reactor types.

■ Table 27

Capacity/availability factors (%) of CANDUs in Korea

Year Unit	2003	2004	2005	2006	2007	2008
Wolsong #1	89.5/88.2	90.3/87.4	77.7/82.9	91.4/91.3	89.8/90.8	93.0/95.5
Wolsong #2	95.3/91.5	94.9/89.8	98.1/94.1	99.7/99.4	90.9/90.7	92.2/92.0
Wolsong #3	97.3/93.3	96.4/91.2	104.5/100.0	94.0/93.7	94.3/94.1	93.0/92.5
Wolsong #4	98.2/94.3	97.4/92.8	98.4/94.2	100.4/100.0	93.2/93.1	94.5/94.2

2.5.1 Wet Storage of Spent CANDU Fuel

After a natural uranium fuel bundle is discharged from the CANDU reactor, having spent about 1 year of irradiation, it is removed to a pool system for interim storage. The water in the pool removes the residual heat produced by the spent fuel and provides radiation shielding for workers. The compact design of the CANDU fuel bundle and the impossibility of criticality occurring for CANDU natural uranium spent fuel bundles under storage conditions in water pools make for extremely simple pool storage.

To ensure protection of the environment and public health, the spent fuel pool in CANDU reactors is provided with double concrete walls, designed such that any leakage through the inner wall would enter drains located between the walls and would flow to the cleanup system. The water acts to shield personnel from the radiation emitted by the spent fuel, and the heat generated by the radioactive decay is transferred to the water. The water is cooled by circulating it through heat exchangers and is purified by passing it through filters and ion exchange systems that remove any dissolved and suspended radionuclides.

2.5.2 Dry Storage of Spent CANDU Fuel

Besides wet storage of spent fuel, the method of dry storage for spent CANDU fuel is currently used (🔗 Fig. 37). Spent fuel that has already been cooled in the spent fuel pool is surrounded by inert gas inside a large cask. These casks are typically steel cylinders that are either welded or bolted closed. Each cylinder is surrounded by additional steel, concrete, or other material to provide radiation shielding to workers and members of the public. There are various dry storage cask system designs. With some designs, the steel cylinders containing the fuel are placed vertically in a concrete vault; other designs orient the cylinders horizontally. The concrete vaults provide the radiation shielding. In Korea, dry storage facilities which are vertical type of concrete vaults with air cooling have been constructed respectively in 1992, 1998, 2002, and 2006 (🔗 Table 28).

3 Conclusions

Since Korea introduced a Westinghouse-designed pressurized light water reactor (PWR) in 1978 and an Atomic Energy of Canada Limited (AECL)-designed pressurized heavy water reactor

Capacity of spent fuel storage in Korea

Facility	Storage type	Capacity (MTU)
Wolsong #1	Wet storage	801
Wolsong #2	Wet storage	706
Wolsong #3	Wet storage	706
Wolsong #4	Wet storage	706
Dry storage	Dry storage	3,061

(CANDU) in 1983 as turnkey projects, she has steadily constructed, operated, and improved nuclear power plants with self-reliant technologies. Sixteen PWRs and four CANDUs are in operation and eight additional PWRs are under construction at the time of this writing. In terms of installed capacity and gross power generation, the current nuclear power portion amounts to 27 and 39% (as of 2006), respectively, of total electricity generation in Korea.

Following the national policy of maintaining PWRs as main reactor type and CANDUs as complementary, Korea focused on and developed PWR technology through the Nuclear Power Plant Standardization Program, which began in 1984 and continued for over 10 years. This effort resulted in the Optimized Power Reactor 1000 (OPR1000) model, that aimed at maximizing operational efficiency and minimizing inadvertent effects on operators and environment by incorporating construction and operating experiences in Korea. Six units of this model are currently in operation and four units are under construction. The core is fueled with PLUS7, a new fuel assembly design with enhanced thermal-hydraulic and nuclear performance and structural integrity. The refueling cycle length is 18 months with gadolinia burnable absorber, achieving maximum discharge rod burnup of 60,000 MWD/MTU.

In the 1990s and 2000s, Korea next developed the Advanced Power Reactor 1400 (APR1400) model. APR1400 is designed to meet the Korean Utility Requirement Document that reflects the ALWR design requirements developed by Electric Power Research Institute (EPRI), European Utilities Organization, and others. Based on the self-reliant technologies and experiences

from the design, construction, operation, and maintenance of OPR1000, the APR1400 model has adopted advanced design features to enhance plant safety and economical efficiency. The advanced design features include a pilot-operated safety relief valve (POS RV), a four-train safety injection system with direct vessel injection (DVI), a fluidic device (FD) in the safety injection tank, an in-containment refueling water storage tank (IRWST), a cavity flooding system for ex-vessel cooling and in-vessel retention, and an external reactor vessel cooling system. Four units of this model are currently under construction in Korea.

The four CANDU reactors in Korea will continue to operate to their design lives with potential life extension. However, no additional new units are expected to be introduced due, in part, to the burden of establishing and maintaining infrastructure related to the unique CANDU technology.

Abstract: This chapter contains detailed description of the design and technical layout of Russian VVER-type reactors. Both the VVER-440 and the VVER-1000 reactor types are described. VVER reactors are a special design of Pressurized Water Reactors with some particular design features listed in the introduction. The most important of them are:

- A hexagonal geometry of the fuel assemblies (FA) with arrangement of the fuel rods in a triangular grid
- Zirconium-niobium alloy as fuel rod claddings material
- Possibility to transport all large-sized equipment by railway to enable a complete manufacturing process under factory conditions (resulting in a limitation of the outer diameter of the reactor pressure vessel)
- An original design of horizontal type steam generators with a tube sheet in the form of two cylindrical heads

VVER reactors are the most frequently built reactor type in the world. Presently, there are 23 units of VVER-440 and 28 units of VVER-1000 worldwide in operation (see tables in ➤ Sects. 2.3 and ➤ 3.3).

In the introduction, a historical overview on the design of VVER-440 and VVER-1000 reactors is given. First units with predecessors of VVER-440 type reactors were erected at the Novovoronezh NPP site in 1972 and 1973. The second step in the development of VVER-440 type reactors was the V-230 design, where the number of mechanical control rods was reduced from 73 to 37 due to introduction of boron as a moderator. In the period from 1973 to 1982, all 14 units were constructed with the V-230 design. The third step in VVER-440 development was V-213 reactor design referred to as the second generation of the standard VVER-440 reactors; their design basis included a double-ended instantaneous guillotine break of the maximum diameter primary pipeline.

The development of VVER-1000 reactors was started by OKB Gidropress in 1966. The first reactor with an electrical power of 1,000 MW was commissioned at Novovoronezh NPP Unit 5 in 1980. In the design, the traditional engineering solutions of VVER were used with the appropriate modernization from the experience obtained in the design, manufacture, and operation of the VVER prototypes. The design concept was oriented to an increase in economic efficiency of the nuclear power plant (NPP) construction and operation, ensuring safety in accordance with the regulatory documents that were valid at the time. An instantaneous double-ended guillotine break of the main coolant pipeline was considered as the maximum design basis accident. The reactor plant was placed into a containment of prestressed concrete.

Further on, the design modifications ended up in elaboration of V-302 Project implemented at the South-Ukraine NPP Unit 1 and V-338 Project implemented at the South-Ukraine NPP Unit 2 and the Kalinin NPP Units 1 and 2. Elaboration of these projects classified as small series designs and their realization was under way from 1976 to 1987.

All the power units of VVER-1000 NPPs, beginning with 1985, were constructed to a standard design that contains the V-320 reactor plant, capable of being sited in seismic areas with earthquakes up to magnitude 9 (SSE), the reactor of small series; D nom 850 circulation loops without gate valves; wet reloading of internals; PGV-1000 horizontal steam generators; and GTsN-195M reactor coolant pumps (large series).

The main feature of the enhanced standard VVER-1000 reactor is the application of jacket-free fuel assemblies (their quantity increased from 151 pcs. to 163 pcs. and the reduction of control rods from 109 to 61 [up to 49 at the South-Ukraine NPP Unit 1]) and the application of ShEM drives in reactor trip system.

The large series designs have been realized since 1978 up to now. Twenty-eight Generation II power units with VVER-1000 have been constructed and are in operation at NPPs.

The accidents at TMI-2 and Chernobyl-4 NPPs have shown that it is necessary to take into consideration the beyond design basis accidents (BDBA) during their design and operation. In 1988 a new V-1000 design was launched (V-392 Project), which focused on safety improvements in response to new requirements of regulatory documents in order to prevent occurrence of BDBAs and to mitigate their consequences in the case that they happened.

The idea was implemented in the RP design of V-392 Project incorporated into NPP-92 design. The main RP equipment of the V-392 design, including the reactor, was implemented in a set of RP V-428 at “Tianwan” NPP. The information on this NPP design was incorporated into the chapter on VVER-1000 reactors. The modifications to V-392 RP design can be found in the design of RP V-412, which are being implemented now at “Kudankulam” NPP. Designs of Units with RP V-392, V-428, and V-412 are referred to Generation III reactors. In both VVER-440 and VVER-1000 sections of the chapter, first, the main design parameters of these reactors are given. Second, the buildings and structures are described that house the reactor plant and auxiliary systems. As a special feature of VVER-440, two power units of this reactor type are incorporated into one main building of the NPP. Further, a tower, being a part of the reactor building with V-213 reactor plant, houses the vacuum-bubbler passive system to reduce pressure in the containment.

Quite comprehensive sections are devoted to the primary circuit systems and equipment. The reactor coolant system, reactor, main circulation pumps, pressurizer, steam generators, and chemical and volume control systems are described. While the VVER-440 reactors dispose of six primary circuit loops, the VVER-1000 has four loops.

Special attention is paid to the core and fuel design. Special features of the VVER-440 core design are the fuel assemblies with housings and control assemblies, which consist of two parts: an absorber part and a fuel follower. When the absorber part is withdrawn from the reactor core, the fuel follower is inserted into the core. In VVER-440, profiled fuel assemblies with Gd_2O_3 burnable absorber are used to decrease the power peaking factor in the core. The control elements for VVER-1000 reactors are of the cluster type, similar to western PWR designs. Typically, 18 absorber rods are placed in a control assembly.

In subsequent sections, the secondary circuit components (Main Steam Line System, Main Feedwater System, Turbine, Generator, and Moisture Separator Reheater) are described. The power units with VVER-440 are equipped with two turbines and generators of 220 MW electrical power and the power units with VVER-1000 have one 1,000-MW-turbine driving one generator.

Further I&C as well as electrical systems are briefly described. The instrumentation and control systems of some of the VVER-440 units have been recently updated. The refurbishments were mainly aimed at the introduction of advanced features for data processing, transmission, and archiving.

In ► Sects. 2.2 and ► 3.2, the safety philosophy and safety systems of VVER-440 and VVER-1000 are described. The applied concept of safety assurance for power units of Generations II and III is outlined. For the Generation III VVER designs, significant improvements were implemented in accordance with the up-to-date international requirements for NPP safety assurance.

The data on the VVER reactors under construction, operation, and decommissioning are presented in ► Sects. 2.3 and ► 3.3.

1 Introduction

VVER-type reactor development was started by OKB “GIDROPRESS” in 1955. The first reactor of 210 MW (el.) power was commissioned at Unit I of Novovoronezh NPP (NV NPP) in 1964. A number of basic engineering solutions developed for the first VVER were of original character and most of them became traditional features for subsequent VVER generations. Such solutions included the following:

- A hexagonal grid for the arrangement of fuel assemblies (FAs) in the reactor core and accordingly the shape of fuel assemblies is hexahedral; the fuel rods in fuel assembly are arranged in triangular grid,
- Zirconium–niobium alloy is used as the material for fuel rod claddings,
- Possibility to transport all large-sized equipment by railway to enable a complete manufacturing process under factory conditions,
- High-strength alloyed carbon steel, which is serviceable in high neutron radiation fluxes, is used as the reactor vessel material,
- The bottom part of reactor vessel, which has no nozzles or any other holes, contains the core,
- The reactor vessel is manufactured of solid-forged shells without longitudinal welds,
- CPS (control and protection system) drives, outlets of temperature and power control systems are arranged on the removable upper head unit of the reactor,
- An original design of horizontal type steam generators with a tube sheet in the form of two cylindrical heads,
- Austenitic stainless steel is used as the material of steam generator HX tubes.

The first VVER core had an equivalent diameter of 2.9 m, a height of 2.5 m, and a thermal power output of 760 MW without any special measures being provided in the design for neutron flux equalization. The resultant operation of the core showed that the capabilities of this design specification were still not exhausted. Using this experience, a reactor with a power of 365 MW (el.), which had a similar core size was designed for Novovoronezh NPP, Unit 2. The design considered measures for the equalization of the neutron flux. This Unit was commissioned in 1969.

The first VVER reactors were designed for a service life of 20 years and were decommissioned in 1984 and 1990, respectively.

The development of VVER-440 reactor started simultaneously with the design of Unit 2 of Novovoronezh NPP. It was assumed as the “standard” version for the construction of a number of NPPs with VVER. The core sizes and design were mainly similar to the VVER-365

reactor. The increase in the electrical power output of the units was mainly due to enhancements of the NPP efficiency relating to modifications to parameters associated with the primary coolant and steam, respectively. This was achieved by the application of other power equipment and some changes to the equipment used in reactor coolant system. The first VVER-440 (B-179) reactors were commissioned at Units 3 and 4 of Novovoronezh NPP in 1971 and 1972, respectively.

The second step in development of VVER-440 type reactors was the V-230 design, where the number of mechanical control rods was reduced from 73 to 37 due to introduction of boron as a moderator. From 1973 to 1982, in all 14 Units were constructed with the V-230 design.

Reactors V-179 and V-230 are referred to as the first generation of the standard VVER-440 reactors. The specifications of these plants provide a high quality of pipelines, equipment, and other reactor plant components that allowed the prevention of significant damage and thus the avoidance of the possibility of breaks in the large diameter primary pipelines. Accordingly, the safety systems of the reactors were designed for a limited size of leak in the primary circuit.

The third step in VVER-440 development was V-213 reactor design referred to as the second generation of the standard VVER-440 reactors; their design basis included a double-ended instantaneous guillotine break of the maximum diameter primary pipeline. The first two Units of this series were constructed at NPP “Loviisa” in Finland in 1977 and 1980, respectively. The containment of these Units presented a shell with ice condensers. The original vacuum-relief system where the building is directly connected to a sealed box of the reactor coolant system is used at other NPPs with V-213 reactor. At present, 16 of such Units are in operation.

The development of VVER-1000 reactors by OKB Gidropress was started in 1966. The first reactor with an electrical power of 1,000 MW (V-187 Project) was commissioned at Novovoronezh NPP Unit 5 in 1980. In the design, the traditional engineering solutions of VVER (see ► Chap. 1.4.A) were used with the appropriate modernization from the experience obtained in the design, manufacture, and operation of the VVER prototypes. The design concept was oriented to an increase in economic efficiency of the NPP construction and operation ensuring safety in accordance with the regulatory documents that were valid at the time. An instantaneous double-ended guillotine break of the main coolant pipeline was considered as the maximum design basis accident, similar to Project V-213. The reactor plant was placed into a containment of prestressed concrete.

Further design modifications resulted in the development of V-302 Reactor Plant, which was implemented at the South-Ukraine NPP, Unit 1, and the V-338 Reactor Plant was implemented at the South-Ukraine NPP, Unit 2, and Kalinin NPP, Units 1 and 2. The development of these projects was classified as “small series” designs and their realization took place between 1976 and 1987.

Since 1985, all Units operated with VVER-1000 have been constructed to a standard design. This included the standard V-320 reactor plant, which could be sited in seismic areas with earthquakes of up to magnitude 9 (SSE), and the standard modernized reactors constructed with the “small series” modifications. The design comprised D_{nom} 850 circulation loops without gate valves; “wet” reloading of internals, horizontal steam generators of Unit 5 of NV NPP; reactor coolant pumps GCN-195M (“large series”).

The main feature of the modernized standard VVER-1000 reactor is the application of jacket-free fuel assemblies with an increase in their number from 151 pieces to 163 pieces. There was also a decrease in the number of control rods from 109 pieces to 61 pieces (to 49 pcs. at South-Ukraine NPP, Unit 1) with CPS pitch electromagnetic drives applied to the control rods.

The “large series” designs have been realized since 1978. On the whole, 28 Units with VVER-1000 reactors have been constructed and they are currently in operation at NPPs. All these Units are referred to as VVER of Generation II.

The accidents at TMI-2 and Chernobyl-4 NPPs have shown that it is necessary to take into consideration the beyond design basis accidents (BDBAs) during their design and operation. This is despite the low probability of such accidents. Appropriate requirements were introduced into the new revisions of the regulatory documents on NPP safety assurance.

In 1988, a new V-1000 design was launched (V-392 Project), which focused on safety improvements in response to new requirements of regulatory documents in order to prevent occurrence of BDBAs and to mitigate their consequences in case they happened.

The idea that was implemented in V-392 Project and incorporated into NPP-92 design was given a EUR certificate. The design modification provided for an engineering embodiment of the safety systems andbdba management systems that conceptually differ through the different ratios of passive and active systems, which are applied for accident management.

The main RP equipment of the V-392 design, including the reactor, is now implemented in a set of RP V-428 at “Tianwan” NPP. Information on this NPP design is incorporated into the chapter on VVER-1000 reactors. The latest modifications to V-392 RP design can be found in the design of RP V-412, which are being implemented now at “Kudankulam” NPP. Units 1 and 2 of “Tianwan” NPP were constructed and commissioned in 2007.

Designs of Units with RP V-392, V-428, and V-412 are referred to as Generation III reactors. Data on the VVER reactors under construction, operation, and decommissioning are presented in ➤ Sects. 2.3 and ➤ 3.3.

2 VVER-440 Reactors

2.1 Design Description

2.1.1 Buildings and Structures

Reactor Building

Two power units of the type VVER-440 are incorporated into the main building of the NPP. The layout of the reactor compartment contains power units, which are reflected through the general transport corridor (➤ *Figs. 1* and ➤ *2*; ➤ *Table 1*).

The main NPP building comprises of the reactor compartment, which includes a system of sealed rooms containing both power units, the turbine hall, a longitudinal stack of electric devices with forced ventilation equipment, two transverse stacks of electrotechnical devices, a stack of special ventilation, and two underground emergency boron inventory tanks. The main building is connected with an auxiliary building by a covered trestle. The trestle is adjoined to the reinforced-concrete ventilation duct of 120 m height. The total length of the reactor compartment comprising two Units with common facilities is 126 m (➤ *Fig. 3*).

All rooms of the main building are separated into two categories: restricted and free access areas according to radiation exposure standards. The rooms of reactor compartment, ventilation stack, and boron emergency inventory tank are defined as restricted areas. The turbine hall, the longitudinal and transverse stacks of electrotechnical devices are the free access areas. The reactor compartment includes the systems of sealed rooms in which both units are contained and between which common-unit rooms are located.

The attended reactor hall is common for both power units. The fresh fuel unit, the spent fuel pool, reactor units unloading, and inspection locations with other equipment for each unit are located in the reactor hall. The spent fuel and handling pool is not included in the system of sealed rooms. However, the outer walls of the pool and bottom floor including the facing on the side of SG box are included in the set of enclosure structures of the sealed rooms. The reactor hall is connected to the transport corridor via the system of removable floors.

The system of sealed rooms of a single unit includes the steam generators box, the reactor concrete cavity, the reactor coolant pump (RCP) and main gate valve(MGV) drives room, the inventory tank of emergency boron solution, and other rooms.

The base with rails for the fuel-handling machine is arranged above the upper part of the reactor concrete cavity and spent fuel pool. The fuel-handling machine is used for both reactor units. Equipment is transferred with the use of traveling cranes that is also common to both reactor units.

A VVER-440 reactor and the associated primary equipment are arranged in each set of sealed rooms in the reactor compartment. The sealed rooms are formed by airtight reinforced-concrete walls with a thickness of 1,500 mm, which are sealed by the covering of metal sheets. A protective bonnet hermetically seals reactor concrete cavity from the reactor hall. The upper part of the reactor unit protrudes into the reactor hall.

The equipment is mounted in the reactor concrete cavity that is intended for biological shielding against core radiation, reactor safe fastening, and thermal insulation. The concrete cavity is separated into top and bottom parts by an annular console. The upper part is connected with spent fuel pool by the transport corridor and is flooded with water during refueling. The upper part of the concrete cavity is isolated from the lower part by concrete truss with

metal bellows. The refueling transport corridor is sealed with a special partition during reactor operation.

In a V-230 reactor plant (► Fig. 4), an annular tank filled with water is used as a reactor vessel support and for the radiation protection of external structures. The tank water volume is 90 m^3 ; the annular thickness is about 1 m. Cooling of the lower part of the concrete cavity and the annular tank is provided with an airflow rate of $50,000 \text{ m}^3/\text{h}$.

As the containment of RP V-230 in the building of the two units arrangement was not designed for the pressure experienced under maximum design basis accident ($D_{\text{nom}} 500$ break), a system of depressurization was introduced into the containment for V-213 reactor plants. This

■ **Figure 5**
Containment of V-213 reactor plant

comprises of an active sprinkler system and passive vacuum-relief system. The vacuum-relief system is located in a special tower for pressure relief (► [Fig. 5](#)).

The V-213 reactor vessel support is a supporting truss, which was designed for the loading conditions it would have received under a break of D_{nom} 500 pipeline. External structural protection against core radiation is provided by the dry shielding made in the form of circular metalwork filled with serpentine concrete.

Unlike the V-230 reactor plant, ducts are provided for emergency steam discharge from the upper part of the reactor concrete cavity into SG box. Gaps can be enlarged in the thermal insulation for performing inspections of the reactor vessel. These gaps are located at the nozzle, the vessel bottom, and the lower part of the vessel (► [Fig. 6](#)).

Pressure Relief Tower

The vacuum-relief system comprises of a relief tank and catching chambers arranged in an independent construction (i.e., the pressure relief tower). The tower dimensions are $39 \times 21.5 \text{ m}^2$ with a height of 41.9 m. The tower is connected with the sealed rooms of reactor compartment with a channel of cross section $11.5 \times 6.2 \text{ m}$ and length of 15 m. The tower with sealed rooms presents a compact closed structure.

The pressure relief tower is a reinforced-concrete structure with a wall and ceiling thickness of 1,500 mm. The tower is separated by a wall axially into the relief tank room, which is $39 \times 8.55 \text{ m}^2$ and rooms of four catching chambers with dimensions of $39 \times 11.45 \text{ m}^2$.

The relief tank room has a total volume of $13,970 \text{ m}^3$ and the total volume of the catching chambers is $16,465 \text{ m}^3$. The inner walls of the relief tank are covered with metal sheets fixed

on structural reinforcement. All inner walls, ceilings, and floors of catching chambers are also covered with metal sheets providing maximum impermeability of the structure.
